Alternative high-yield preparations of many other derivatives were later developed, on the basis of the cleavage of Re–Re multiple bonded complexes, a reaction normally promoted by  $\pi$ -acceptors such as CO, NO, and CNR. In this way, homoleptic  $[\text{Re}(\text{CNR})_6]^+$  (**153**) derivatives ( $\text{R} = \text{alkyl}$ ,  $\text{aryl}$ ) and  $\text{ReX}(\text{CNAr})$  are obtained in excellent yields from  $\text{Re}_2(\text{O}_2\text{CMe})_4\text{Cl}_2$ . Mixed derivatives  $[\text{Re}(\text{CNR})_4(\text{PR}_3)_2]^+$  (**154**) are likewise prepared from  $\text{Re}_2\text{Cl}_4(\text{PR}_3)_4$  and are not

directly available from (**153**) because of its substitutional inertness. However, in the case of  $\text{Re}_2\text{Cl}_4(\text{LL})_2$  analogs ( $\text{LL} = \text{dppm}$  or  $\text{dppe}$ ) where the diphosphine ligands bridge the two metals, reaction with CNR gives the adduct  $\text{Re}_2\text{Cl}_4(\text{LL})_2(\text{CNR})$  with a bridging Cl atom. Additional CNR replaces Cl, giving  $[\text{Re}_2\text{Cl}_3(\text{LL})_2(\text{CNR})_2]^+$ , but the Re–Re bond retains its multiple character. This chemistry was later extended to CO and NCR and mixed-ligand analogs with emphasis on their structural characteristics.<sup>186</sup>

Alternatively, high yields of (**154**) are obtained by the reaction of the polyhydrides  $\text{ReH}_7(\text{PR}_3)_2$  or  $\text{ReH}_5(\text{PR}_3)_3$  with CNR. In Section 3.1, reference was made to a large number of complexes of the type  $[\text{ReH}_x(\text{PPh}_3)_2(\text{CNR})_y]^n$ . These compounds are prepared from polyhydrides and CNR, as illustrated in the reaction sequence of Scheme 34.

Pombeiro has shown that irradiation of  $\text{ReCl}(\text{N}_2)(\text{dppe})$  in the presence of a variety of CNR ligands leads to  $\text{ReCl}(\text{CNR})(\text{dppe})_2$ , which gives  $[\text{ReL}(\text{CNR})(\text{dppe})_2]^+$  ( $\text{L} = \text{CO}$ ,  $\text{CNR}$ ) upon treatment with  $\text{TI}^+$  salts in the presence of ligand, L. Electrophilic reactions of these compounds have been used as models of *Nitrogen Fixation* by low-oxidation state metal centers and will be discussed below.

As mentioned in Section 2.4.2, 17-electron, mononuclear  $\text{Re}^{\text{II}}$  complexes are rare, in contrast to the multiply bonded  $\text{Re}_2\text{X}_4(\text{PR}_3)_4$ . A few representative examples were prepared by Walton either by oxidation of the parent  $\text{Re}^{\text{I}}$  complexes, for example,  $[\text{Re}(\text{CNAr})_6]^{2+}$  from  $[\text{Re}(\text{CNAr})_6]^+$ , or by reduction of  $\text{Re}^{\text{III}}$  species with CNR.<sup>3</sup>

$\text{Re}^{\text{III}}$  isocyanide derivatives are relatively abundant either as six- or seven-coordinate species. They may be prepared, as in the case of the carbonyls, by oxidative addition to  $\text{Re}^{\text{I}}$  precursors, for example,  $\text{ReBr}_3(\text{CNR})_4$  from  $\text{ReBr}(\text{CNR})_4(\text{CO})$  and  $\text{Br}_2$ , by nonreductive cleavage of Re–Re bonds, by reacting  $[\text{Re}_2\text{Cl}_8]_2$  or  $\text{Re}_2\text{Cl}_6(\text{PR}_3)_2$  with CNR, giving  $[\text{ReX}_2(\text{CNR})_5]^+$  and  $[\text{ReX}_2(\text{CNR})_4(\text{PR}_3)]^+$ , respectively, by substitution reactions, for example, from *mer*- $\text{ReX}_3(\text{PR}_3)_3$  to give  $[\text{ReX}_2(\text{CNR})_3(\text{PR}_3)_2]^+$  and by reduction of  $\text{ReOCl}_2(\text{PPh}_3)_2$  with  $\text{PPh}_3$  to give  $\text{ReCl}_2(\text{CNR})(\text{PPh}_3)_2$ .  $\text{ReCl}_3(\text{CNMe})_3$  and trinuclear species  $\text{Re}_3\text{X}_9(\text{CNR})_3$  are also known.<sup>50</sup> In the mononuclear complexes, seven coordination achieves the 18-electron configuration and is typically a capped octahedron with a CNR ligand capping one of the faces. Upon loss of a two-electron ligand, octahedral 16-electron species are formed, of which all *trans*- $[\text{ReCl}_2(\text{CN-}i\text{-Pr})_2(\text{PMePh}_2)_2]^+$  complexes were the first to be structurally characterized. This complex readily adds CO or CN-*i*-Pr to generate seven-coordinate species.<sup>50</sup> Re–CNR complexes in higher oxidation states, for example,  $[\text{ReCl}_5(\text{CNMe})]^-$  are very rare.<sup>2</sup>

Scheme 34

In contrast with the thermal substitutional inertness, photolysis of  $[\text{Re}(\text{CNAr})_6]^+$  in the presence of  $\text{X}^-$  gives  $\text{ReX}(\text{CNAr})_5$ . Like the isoelectronic CO, coordinated CNR may undergo nucleophilic addition of  $\text{Y}^-$  to give the corresponding iminoacyls  $[\text{ML}_n\{\text{C}(\text{NR})\text{Y}\}]^-$  that produce Fischer-type carbenes  $[\text{ML}_n\{\text{C}(\text{NR})(\text{YR})\}]$ . The electrophilicity of the coordinated C atom in CNR is obviously enhanced in cationic complexes and when electron-withdrawing R groups are present. Competition between nucleophilic addition at CO and CNR in the same metal has been studied on the basis of electronic effects, but the steric bulk of the R group also plays a role. Addition of  $\text{H}_2\text{NR}$  to  $\text{ReBr}(\text{CO})_4(\text{CNR})$  confirmed attack at CNPh to form the diaminocarbene complex  $\text{ReBr}(\text{CO})_4\{\text{C}(\text{NHPh})(\text{NHR})\}$ .<sup>187</sup>

Stressing the importance of the charge and other electronic balances,  $[\text{Re}(\text{CO})_5(\text{CN}-t\text{-Bu})]^+$  is found to react with nucleophiles, including amines, but preferentially at a *cis*-CO ligand to give the carbamoyl derivatives *cis*- $[\text{Re}(\text{CO})_4(\text{CNR})\{\text{C}(\text{O})\text{NHR}\}]$ . The complex  $\text{ReBr}(\text{CO})_3(\text{CNPh})(\text{CNN}=\text{CMe}_2)$  (**155**) reacts with  $\text{H}_2\text{N}-i\text{-Pr}$  preferentially at the N-isocyanoiminoalkane ligand to give  $\text{ReBr}(\text{CO})_3(\text{CNPh})\{\text{C}(\text{NH}-i\text{-Pr})(\text{NHN}=\text{CMe}_2)\}$ , but a further attack at the CNPh ligand occurs readily to give the biscarbene  $\text{ReBr}(\text{CO})_3\{\{\text{C}(\text{NH}-i\text{-Pr})\text{NPh}\}\{\text{C}(\text{NH}-i\text{-Pr})(\text{NHN}=\text{CMe}_2)\}\}$ . (**155**) is obtained by the Wittig reaction of  $\text{ReBr}(\text{CO})_3(\text{CNPh})(\text{CNNPPH}_3)$  with acetone.<sup>188</sup>

The CNNPR<sub>3</sub> ligand still has a rather undeveloped chemistry. The chemistry of aminocarbenes derived from isonitriles by nucleophilic addition has been reviewed.<sup>189</sup>

Electrophilic addition to coordinated CNR has been observed when it is ligated to very electron-rich metal centers. The structures of several of these complexes show severe bending of the C–N–R angle, between ca. 140 and 160°, and the (C≡N) stretching vibrations appear at rather low energies (ca. 1830  $\text{cm}^{-1}$ ) compared to normal linear CNR ligands of free CNR (2150  $\text{cm}^{-1}$ ). Both effects are explained by the importance of the bonding structure (**157**) of the two bonding extremes, (**156**) and (**157**), which shows the carbene character of the Re–C bond in these complexes.

More pronounced bending is systematically observed when the ligand trans to a CNR ligand is not a  $\pi$ -acceptor, for example, CNR being trans to Cl in  $\text{ReCl}(\text{CNMe})_3(\text{PMePh}_2)_2$  (**158**) contrasted to being trans to NCMe in  $[\text{Re}(\text{NCMe})(\text{CNMe})_3(\text{PMePh}_2)]^+$ . The structure (**157**) also points to the nucleophilic character of the N atom that may be protonated to give aminocarbynes. The first such complex was reported in 1981 by the protonation of  $(\text{ReCl}(\text{CNR})(\text{dppe})_2)$  with  $\text{HBF}_4$  to give *trans*- $[\text{ReCl}(\text{CNHMe})(\text{dppe})_2]\text{BF}_4$ . Examples formally derived

from the protonation of (**158**), but actually prepared by Zn reduction of  $[\text{ReCl}_2(\text{CNR})_3(\text{PMePh}_2)_2]^+$  in the presence of traces of water, have been reported as fully characterized compounds and compared with analogs of other metals, for example, Mo, W, and Fe. The simplest aminocarbyne has also been characterized in  $[\text{ReCl}(\equiv\text{CNH}_2)(\text{dppe})_2]\text{BF}_4$  as prepared from the parent CNH or CNTMS complexes.

The crystallographic data also stresses the important carbenic character of the aminocarbyne–metal bond ( $\text{Re}=\text{C}=\text{NHR}$ ) inasmuch as the NHR group is planar and the C–N bond distance is appropriate for a C=N bond. The chemistry of aminocarbynes has been thoroughly reviewed.<sup>190</sup>

Protonation of the CNR ligand in complexes  $\text{Re}\{\text{N}(\text{CH}_2\text{CH}_2\text{S})_3\}(\text{CNR})$  in aqueous HCl leads to the unprecedented transformation of CNR into CO producing  $\text{Re}\{\text{N}(\text{CH}_2\text{CH}_2\text{S})_3\}(\text{CO})$  ( $\text{R} = t\text{-Bu}, \text{CH}_2\text{COOEt}$ ). Again, the CNR ligand is strongly bent in these complexes and does not undergo nucleophilic addition at its C atom.<sup>191</sup>

### 13 CHEMISTRY OF Re NITROSYL COMPLEXES

The main role of the  $\text{NO}^+$  ligand in organorhenium chemistry has been the replacement of CO in  $\text{ML}_n\text{CO}$  complexes to generate isoelectronic and isostructural metal nitrosyl complexes with one added unit of positive charge, for example, cationic  $[\text{ML}_n\text{NO}]^+$  species. The effect of the  $\pi$ -acidity of  $\text{NO}^+$  and an increased positive charge of the complex strongly activates the unsaturated ligands toward nucleophiles. The results of these effects are evident in the differences between the chemistries of  $\text{ReCp}(\text{CO})_2$  and the fragments  $[\text{ReCp}(\text{CO})(\text{NO})]^+$  or  $[\text{ReCp}(\text{NO})(\text{PPh}_3)]^+$ . In fact, while the alkenes in  $[\text{ReCp}(\text{CO})_2(\eta^2\text{-alkene})]$  undergo an electrophilic attack, in  $[\text{ReCp}(\text{NO})(\text{PPh}_3)(\eta^2\text{-alkene})]^+$  the reverse reaction, that is, nucleophilic addition, is observed. A complementary example of these ideas has been developed by Wieghardt from the systems  $[\text{Re}(\text{tacn})(\text{CO})_3]^+$  (**159**) and  $[\text{Re}(\text{tacn})(\text{CO})_2(\text{NO})]^{2+}$  (**160**), which display a reactivity parallel to both isoelectronic cyclopentadienyl congeners. Complex (**159**) generates  $[\text{Re}(\text{tacn})\text{O}_3]^+$  with  $\text{H}_2\text{O}_2$ , and (**160**) reacts with  $\text{NaBH}_4$  to give racemic  $[\text{Re}(\text{tacn})(\text{CO})(\text{NO})\text{CH}_3]^+$  (**161**), which has been resolved into its pure enantiomers.

The most useful precursors are the dimers  $[\text{ReCl}_2(\text{CO})_2(\text{NO})]_2$ , (**162**)  $\text{ReCl}_2(\text{OR})(\text{PPh}_3)_2(\text{NO})$  (**163**), and  $\text{ReH}_2(\text{PPh}_3)_3(\text{NO})$  (**164**). Substitution or addition reactions on (**162**) give the dibromide, diiodide, and  $\beta$ -diketonate derivatives,  $\text{ReCl}_2(\text{CO})_2\text{L}(\text{NO})$ ,  $\text{ReCl}_2(\text{CO})\text{L}_2(\text{NO})$  complexes with a variety of two-electron ligands, L, and  $\text{ReR}_2(\text{CO})\text{L}_2(\text{NO})$  ( $\text{R} = \text{H}, \text{Me}$ ).<sup>192</sup>

Cationic complexes of formulae,  $[\text{Re}(\text{NO})\text{XL}_3(\text{CO})]^+$  and  $[\text{Re}(\text{NO})\text{L}_4(\text{CO})]^{2+}$  as well as the triflates  $\text{Re}(\text{NO})\text{L}_2(\text{CO})(\text{OTf})_2$  are obtained upon halide abstraction from  $\text{ReCl}_2(\text{CO})\text{L}_2(\text{NO})$ .<sup>193</sup>

Scheme 35

Complex (**163**) reacts with other L ligands to give  $\text{ReCl}_2(\text{PPh}_3)_2\text{L}(\text{NO})$  and with  $\text{NaBH}_4$  to afford (**164**). This latter compound reacts with CO to give  $\text{Re}(\text{CO})_2(\text{PPh}_3)_2(\text{NO})$ . With strong protic acids HX, in ROH, reaction of (**164**) forms  $\text{ReH}(\text{OR})(\text{CO})(\text{PPh}_3)(\text{NO})$  ( $\text{X} = \text{ClO}_4$ ) and  $\text{ReHF}(\text{CO})(\text{PPh}_3)_2(\text{NO})$  ( $\text{X} = \text{BF}_4$ ). The spectroscopic and chemical properties of  $\text{ReH}_2(\text{NO})(\text{CO})(\text{PR}_3)_2$  and similar complexes has been thoroughly studied by Berke. The high-yield synthesis of  $[\text{ReBr}_5(\text{NO})][\text{NEt}_4]_2$  provided the most recent entry to the chemistry of NO containing hydrides in several oxidation states.  $\text{Re}(\eta^2\text{-H}_2)\text{Br}_2(\text{NO})(\text{PR}_3)_3$ ,  $\text{ReH}(\text{BH}_4)(\text{NO})(\text{PR}_3)_2$ ,  $\text{ReH}_2(\text{NO})(\text{PR}_3)_3$ , and  $\text{ReH}_4(\text{NO})(\text{PR}_3)_2$   $[\text{ReH}_3(\text{NO})(\text{PR}_3)_2]^-$  are interrelated by simple chemical transformations ( $\text{R} = i\text{-Pr, Cy}$ ). Reaction of  $\text{ReH}(\text{BH}_4)(\text{NO})(\text{PR}_3)_2$  with  $\text{NOBF}_4$  leads to  $\text{ReH}(\text{NO})_2(\text{PR}_3)_2$  via the isolable intermediate  $\text{ReH}(\text{NO})(\text{NOBF}_3)(\text{PR}_3)_2$  (**165**).<sup>194</sup>

In most of the chemistry of the NO complexes, its influence has been considered as stemming from its outstanding  $\pi$ -acidity and from its noninnocent behavior as either a one (bent) or three (linear) ligand. However, (**165**) clearly reveals the Lewis basicity of the O atom of the NO ligand that is also shown to engage in hydrogen bonding with Re–H bonds.<sup>61</sup>

Indeed, the complexes *trans*- $\text{Re}(\text{NO})(\text{CO})_2(\text{PR}_3)_2$  are protonated by HCl at the NO to give the nitroxyl derivatives *trans*- $\text{ReCl}(\text{HN}=\text{O})(\text{CO})_2(\text{PR}_3)_2$  that are reversibly deprotonated by N-bases. This allowed the study of the properties of coordinated nitroxyl, a most unstable molecule.<sup>195</sup>

NO induces a strong hydridic polarization of the Re–H bond in nitrosyl hydrides, the ‘nitrosyl effect’. The conjugation of these properties enables them to perform the heterolytic cleavage of  $\text{H}_2$  and  $\text{R}_3\text{Si-H}$  bonds as depicted in Scheme 35 as well as the insertion of Re–H bonds into polar unsaturated organic substrates.<sup>196</sup>

A bent NO adduct of  $\text{ReCp}_2^*$  is in agreement with the expected coupling of two radicals to form a two-electron Re–NO bond.<sup>141</sup>

The thionitrosyl  $[\text{Re}(\text{CO})_5(\text{NS})]^{2+}$  adds halides to give  $[\text{Re}(\text{CO})_5(\text{NSX})]^+$  ( $\text{X} = \text{F, Cl, Br}$ ).<sup>197</sup>

## 14 POLYNUCLEAR Re ORGANOMETALLIC COMPLEXES

Besides the classical donor atoms, C, O, N, P, S, and the halides, Re forms organometallic complexes containing

practically all other metals and *Metalloids*, a class that may be broadly classified under the heading of *Polynuclear Complexes*. The number and structural variety of these species is overwhelming and has grown dramatically, along with the development of X-ray diffraction techniques as the ultimate tool for the characterization of often totally unexpected and/or new bonding modes and structural arrangements. The progress of the Re–CO cluster chemistry (Section 3.2) is paradigmatic. Among the several existing possibilities of subclassifications within this class of compounds, the existence of direct Re–M' bonds ( $\text{M}' = \text{main group or d or f transition element}$ ) is adopted below. This classification has, however, rather weak boundaries. In fact, some Re–M' bonds may be only formal or simply required by the *Effective Atomic Number Rule*, and complexes that have no such bonds may readily form them by simply losing a ligand, sometimes in a facile or reversible manner. Because of the extreme variety of compounds, only a few selected examples, mainly from the more recent literature, are presented. The use of other reviews is absolutely necessary to cover this field.<sup>2–7</sup>

### 14.1 Organometallic Polynuclear Re Complexes Containing Other Metals or Metalloid M' without Re–M' Bonds

These types of complexes have the general formula  $\text{L}_n\text{Re-Y-M}'\text{L}'_m$  and at least one of the fragments is organometallic or the bridge has M–C bonds. They may be prepared in one of the following general, but not exclusive, ways: (1) a Re complex behaves as an electrophilic center for ligand substitution from an  $\text{L}'_m\text{M}'$  complex bearing nucleophilic ligands; (2) nucleophilic addition of  $\text{L}_n\text{Re}$  to an unsaturated ligand on the M' complex; and (3) addition of the ligands in  $\text{L}_n\text{Re}$  to  $\text{L}'_m\text{M}'$ . Examples of each type are mentioned along the preceding sections.

The complexes  $\text{Re}(\text{CO})_3(\text{HM}'(\text{pz})_3)$  ( $\text{M}' = \text{B, Ga}$ ) represent a trivial example of the first situation. However, the use of transition metal complexes as ligands is currently receiving more detailed attention, because of the possibility of either tuning the reactivity of the Re in the resulting complex by means of the influence of M' on the ligand or by obtaining cooperative reactivity between the two metal centers. Reaction of ferrocenyl derived ligands, for example,  $\text{Fe}(\eta^5\text{-C}_5\text{H}_4\text{PR}_2)_2(\text{FcPPh}_2)$  with  $[\text{ReX}(\text{CO})_4]_2$  affords *fac*- $[\text{Re}(\text{CO})_3\text{Cl}(\text{FcPPh}_2)_2]$ . Upon ferrocene-based oxidation, the Re electronic density is lowered, as shown by the increase in the  $\nu(\text{CO})$  vibration frequencies. The use of anionic organometallic ligands is also exemplified by the formation of  $[\text{W}(\text{CO})_5(\mu\text{-PPh}_2)\text{Re}(\text{CO})_5]^-$  (**166**) from  $\text{ReX}(\text{CO})_5$  and  $[\text{W}(\text{CO})_5(\text{PPh}_2)]^-$ . A related example is the formation of  $\text{Re}(\text{CO})_5(\mu\text{-O})\text{Re}(\text{O})_3$  from  $\text{Re}(\text{CO})_5\text{FBF}_3$  and  $\text{ReO}_4^-$ . The second method exploits the high nucleophilicity of  $[\text{Re}(\text{CO})_5]^-$ , which adds to organometallic cations with unsaturated ligands in a similar fashion to  $\text{R}^-$  or  $\text{H}^-$  as extensively studied by Beck. Examples are the formation of complex (**167**)

and analogs. The complexes formed from the ligands (117) and (118) are examples of the third method.

#### 14.2 Organometallic Re Complexes Containing Re–M' Bonds to Metals or Metalloid M'

This class of compound has a very high number of representatives for two main reasons: (1) the interest in cluster chemistry and the study of the systematic pathways for their construction; and (2) the fact that many reactions initially give products without M–M' bonds, but subsequently form M–M' bonded species to compensate for electronic deficiencies.

The extreme complexity of boron chemistry provides a wide variety of B–Re bonds, from simple  $[\text{Re}(\text{BH}_3)(\text{CO})_5][\text{NEt}_4]$  to more complex examples as (138) and (139).<sup>2,3</sup> Simple acid-base addition from  $\text{ReCp}_2\text{H}$  to  $\text{AlMe}_3$  gives an adduct with a Re–Al bond, while with  $\text{Cu}^{\text{I}}$  a tetranuclear species is formed. Reaction of Ga and In metals or compounds with  $\text{Re}_2(\text{CO})_{10}$  produce high nuclearity clusters.<sup>2,52</sup>  $\text{ReM}'$  ( $\text{M}' = \text{Zn}, \text{Cd}, \text{Hg}$ ), as in  $[\text{Re}(\text{CO})_5]_2\text{M}'$ , are well known. With the group 14 elements, many compounds are known. Oxidative addition of  $\text{R}_3\text{M}'\text{--H}$  bonds to  $\text{ReCp}(\text{CO})_3$  under photolysis gives  $\text{ReHCp}(\text{CO})_2(\text{M}'\text{R}_3)$  ( $\text{M}' = \text{Si}, \text{Ge}, \text{Sn}$ ). A number of Ge and Sn compounds of type  $\text{Re}(\text{CO})_5(\text{M}'\text{R}_3)$  and  $\text{Re}(\text{CO})_3(\alpha\text{-diimine})(\text{M}'\text{R}_3)$  have been prepared from  $[\text{Re}(\text{CO})_3\text{L}_2]^-$  and  $\text{M}'\text{XR}_3$  and their photophysics have been studied.<sup>2</sup> However, the most varied class of Re–M' bonded complexes concerns the transition metals M'. According to Roberts and Geoffroy, these complexes are prepared by 17 synthetic methods divided into four main reaction categories: ligand substitution, addition, condensation, and bridge-assisted reactions.<sup>2</sup> This phenomenological classification does not account for mechanistic distinctions within each subcategory.

The use of carbonylate anions as nucleophiles in substitution reactions at metals has been used for a long time to prepare other Re–M' metal-bonded derivatives, for example,  $\text{ReCo}(\text{CO})_9$  from  $[\text{Re}(\text{CO})_6]^+$  and  $[\text{Co}(\text{CO})_4]^-$  and (168) from  $[\text{ReBr}(\text{CO})_4]_2$  and  $[\text{Fe}(\text{CO})_4\{\text{C}(\text{O})\text{R}\}][\text{NMe}_4]$ .<sup>198</sup>

Addition of a metal fragment across a M–M or M–ligand bond is a very general and usually predictable method of preparing M–M' bonded complexes. Among the latest Re complexes prepared by this method, (169) displays a rather interesting chemistry, hydrogenating alkynes to alkenes and providing the best route, so far, to  $\text{ReCp}(\text{CO})_2(\eta^2\text{-alkene})$  complexes. The mechanism of this kind of rare, effective cooperative catalysis in heterobimetallic complexes has been studied in detail.<sup>199</sup> The third general pathway, condensation reactions, forms a M–M bond through the elimination of a small molecule. Alkane elimination is quite useful and a classical example in Re chemistry is the formation of (170) from  $\text{ReCp}_2\text{H}$  and  $\text{MnMe}(\text{CO})_5$  under elimination of  $\text{CH}_4$ .

A more straightforward elimination is observed in the reaction of  $\text{MCp}_2(\text{THF})\text{Me}$  and  $\text{ReH}_7(\text{PPh}_2)_2$  ( $\text{M} = \text{Y}, \text{Lu}$ ), which gives  $\text{MCp}_2(\text{THF})(\mu\text{-H})_2\text{ReH}_4(\text{PPh}_3)_2$ . In this case, there is no M–M' bond, although a close M–Re distance is measured.<sup>200</sup>

$\text{H}_2$  elimination is involved in the formation of  $(\text{PhMe}_2\text{P})_3(\text{CO})\text{ClRe}(\mu\text{-H})\text{Au}(\text{PPh}_3)$  with a rare Re–Au bond.<sup>201</sup> Polyhydrides react with unsaturated metal fragments to originate polynuclear complexes by addition, substitution with  $\text{H}_2$  elimination, or redox processes.  $\text{H}_2$  elimination accompanies the reaction between (28) and  $[\text{IrH}_2(\text{Me}_2\text{CO})_2(\text{PPh}_3)_2]^+$  to give  $[(\text{PPh}_3)_2\text{H}_3\text{Re}(\mu\text{-H}_3)\text{IrH}(\text{PPh}_3)_2]^+$ . (171) represents the product of the addition of  $[\text{AuPPh}_3]^+$  to  $[\text{Re}_3\text{H}_4(\text{CO})_9(\text{PPh}_3)]^-$ .<sup>202</sup>

The central issue of the bridge-assisted mechanism is the presence of a ligand that brings the two metals together and favors the M–M' bond formation by occupying a bridging position in the final product. The complex (166) is 'en route' to this mechanism and upon loss of a Re-bound CO forms a Re–W bond (172). Very important cases of the bridge-assisted M–M' bond formation are the addition of  $\text{M}'\text{L}_n$  fragments to  $\text{M}=\text{CR}_2$  and  $\text{M}\equiv\text{CR}$  fragments. This method

provides the rationale for the construction of clusters with many metal combinations containing bridging carbene and carbyne ligands. Addition of  $\text{Re}_2(\text{CO})_{10}$  to  $\text{WCp}(\text{CO})_2(\text{C}\equiv\text{Ar})$  (**173**), commonly used for this purpose, gives (**174**). However, again depending on the lability of the metal centers involved, reaction of (**173**) with  $\text{Re}_2(\mu\text{-H})(\mu\text{-CH=CHBu})(\text{CO})_8$  gives higher nuclearity structures due to the facile loss of 1-hexene.  $[\text{ReCp}(\text{CO})_2(\equiv\text{CAr})]^+$  has been used for the construction of related clusters. Nucleophilic addition of a wide range of metal-carbonylate anions to the alkylidyne C atom of this very sensitive and reactive cation, at low temperatures, is followed by rearrangements producing a variety of clusters with  $\text{Re-M'}$  bonds. Carbonylates include, for example,  $[\text{M}(\text{CO})_5]^-$  ( $\text{M} = \text{Mn}, \text{Re}$ ),  $[\text{Co}(\text{CO})_4]^-$ ,  $[\text{CpM}(\text{CO})_3]^-$  ( $\text{M} = \text{Mo}, \text{W}$ ),  $[\text{CpFe}(\text{CO})_2]^-$ , and some of the complexes formed are depicted in (**175–177**).

Further reactions of these complexes lead to higher nuclearity clusters, for example, (**178**).

Reactions with carbonylate dianions, for example,  $[\text{W}(\text{CO})_5]^{2-}$ ,  $[\text{Fe}_2(\text{CO})_8]^{2-}$ , and others, also produce a rich cluster chemistry. Ligands other than CO can be included in the carbonylate anions, for example, NO,  $\text{PR}_3$ , SR, SCN, NCO, and CN increasing the scope of cluster derivatization of these synthetic procedures as in (**179**).<sup>203</sup>

Of particular interest has been the study of  $\text{Pt}_x\text{Re}_y$  clusters due to their importance in petroleum refining where the Re seems to counteract the formation of unreactive coke, which poisons the Pt catalyst. A review covers this chemistry and structures (**180–183**) represent some examples.<sup>204</sup>

## 15 BIOORGANOMETALLIC CHEMISTRY OF RHENIUM

This fascinating and fast growing field, already amply reviewed,<sup>205–209</sup> takes advantage of the properties of a wide number of organometallic complexes using them as tools for biological applications. These range from metal immunoassays to drugs, radiopharmaceuticals for imaging and therapy passing through applications in peptide synthesis and peptide marking for X-ray diffraction, electronic microscopy, and other purposes. In the case of Re, one of the earliest examples was the condensation of Lukehart's rhenametalla- $\beta$ -diketones (Scheme 13) with aminoacids to produce  $\alpha$ -ketoimine complexes and, therefore provide for amino protection of those aminoacids. Later on, Jaouen and collaborators realized that the high stability of many CO-containing organometallics to air and to physiological conditions enabled their use in the carbonylmetal immunoassay (CMIA) technique. Taking advantage of their extremely intense CO vibrations in the IR region ( $1900\text{--}2100\text{ cm}^{-1}$ ) where biological molecules do not absorb, steroids, hormones, or drugs labeled with  $\text{M}(\text{CO})_n$  fragments can be detected by FTIR in the  $10^{-12}\text{ M}$  range and are well recognized by their antibodies.

CMIA avoids radioisotopes and allows simultaneous parallel assays.<sup>210</sup>

The CMIA work with steroids marked with  $\text{Re}(\text{CO})_3$  led to the early recognition of the potential of this class of compounds for the diagnosis and therapy of steroid receptor-positive breast cancer. Complex (184) shows higher binding to estrogen receptors than the parent steroid. Complex (185) also binds to the tamoxifen receptor and shows an antiproliferative action comparable to hydroxytamoxifen, a potent breast cancer drug.<sup>211</sup>

This great ability to selectively target metal pharmaceuticals has led to the possibility of using radioactive compounds to deliver radiation in specific receptors, tissues, organs, or cancer sites. The  $\gamma$ -ray emission and short half-lifetime make  $^{99\text{m}}\text{Tc}$  the preferred element for imaging, whereas  $\beta$ -emitting  $^{186}\text{Re}$  (5 mm range) and  $^{188}\text{Re}$  (11 mm range) are preferred for radiotherapeutic purposes (tissue destruction).

As a consequence, Re chemistry has grown parallel to that of Tc using both organometallic and classical coordination complexes. A target-specific radiopharmaceutical must possess high affinity for the selected target but not for others. The 'unnatural' character of organometallic compounds might create distinct advantages compared with 'natural' drugs, which are often subject to unwanted rapid metabolism in vivo. Furthermore, the complex must be thermodynamically and kinetically stable to avoid decomposition and allow for rapid clearance in vivo. This is an advantage of the *fac*- $\text{Re}(\text{CO})_3$  core over other  $\text{Re}^{\text{V}}$  classical complexes since it is particularly inert specially when bound to a *fac*-tripodal ligand system ( $\text{L}_3$  or Cp) with an overall octahedral geometry.

Therefore, the bioorganometallic Re complexes comprise two main classes: the  $(\text{CpX})\text{Re}(\text{CO})_3$  derivatives where CpX

represents the Cp ligand substituted with a bioactive molecule with or without an appropriate spacer, for example, a steroid, a protein, a peptide; the *fac*- $\text{Re}(\text{CO})_3\text{L}_3$  derivatives coordinated to classical N, P, O, S donors that may carry bioactive molecules of the types described above. (186; TROTEC-1) is a tropane derivative with an extremely high affinity for human dopamine transporter and (187) has a high affinity for the serotonergic receptors.

The synthesis of these complexes poses particular problems in the case of the  $(\text{CpX})\text{Re}(\text{CO})_3$  derivatives because the methods to introduce delicate X functions either in a  $\text{CpRe}(\text{CO})_3$  complex or binding CpX to low-valent  $\text{Re}(\text{CO})_3$  precursors like (1) or  $\text{ReX}(\text{CO})_5$  require multistep procedures and/or reaction conditions incompatible with the presence of sensitive X groups. The situation becomes even more difficult when dealing with radioactive isotopes where fast, high-dilution and high-yield methods, and aqueous saline solutions are required.

This situation spurred the search for a number of alternative synthetic methods that have opened new avenues in the field of Re (and Tc) organometallic synthesis.

Still on classic grounds, the use of fulvenes or McMurry coupling to cymantrene ketyl to introduce substituents to the Cp ring in a mild fashion has produced several biologically labeled derivatives.<sup>212</sup>

Among several other methods, Katzenellenbogen developed one-pot reactions of three components like the one in Scheme 36.<sup>213</sup> Alternatively,  $(\text{CpX})\text{SnBu}_3$  can be generated and reacted in situ with  $[\text{Re}(\text{CO})_3\text{Br}(\text{THF})]_2$ .

A major development was introduced by Alberto with the generation of the  $\text{Re}(\text{CO})_3$  moiety in aqueous solution from  $[\text{ReO}_4]^-$ ,  $\text{BH}_3$ , and 1 atom of CO. The resulting  $[\text{Re}(\text{CO})_3\text{X}_3]^{2-}$  ( $\text{X} = \text{Cl}, \text{Br}$ ) is easily transformed into  $[\text{Re}(\text{CO})_3\text{L}_3]^+$  ( $\text{L} = \text{NMe}, \text{H}_2\text{O}$ ). Treatment of aqueous  $[\text{Re}(\text{CO})_3(\text{H}_2\text{O})_3]^+$  with  $[\text{CpX}]^-$  at pH 7.4 gives

Scheme 36

(CpX)Re(CO)<sub>3</sub> where X is an acyl group (–COR) in which R carries the biomolecules of interest to target the Re(CO)<sub>3</sub> fragment to the required biological site.<sup>214</sup> The so-called double-ligand-transfer reactions also provide a mild synthesis of (CpX)Re(CO)<sub>3</sub> derivatized with biomolecules.<sup>215</sup>

Labelling of proteins and peptides with CpRe(CO)<sub>3</sub> fragments can be made by peptide bond formation with the carboxylic acid Re(CpCOOH)(CO)<sub>3</sub> or by acylation of free amine groups with organometallic succinimidyl esters.

Among the [Re(CO)<sub>3</sub>L<sub>3</sub>]<sup>+</sup> complexes bearing ligand systems (L<sub>3</sub>) functionalized with biomolecules, recent advances include fatty acids attached to Schiff-base ligands for myocardial investigations,<sup>216</sup> peptides attached to histidine complexes,<sup>217</sup> (188) or glucose derivatives (189).<sup>218</sup> Luminescent complexes [Re(CO)<sub>3</sub>(N–N)(Py-spacer-biomolecule)]<sup>+</sup> are powerful fluorophores for bioassays since the biomolecule does not interfere negatively with the luminescence from the metal fragment.<sup>42</sup>

Organometallic compounds appear to be a serious alternative to state-of-the-art labeling techniques as shown in the ongoing preclinical and clinical studies with organometallic-labeled tumor affine peptides and single-chain antibody fragments.<sup>219</sup>

## Glossary

*Aqua regia*: literally ‘royal water’, so called because it will dissolve gold; a mixture of three parts concentrated hydrochloric acid to one part concentrated nitric acid

*Corundum structure*:  $\alpha$ -aluminum oxide structure

*Electrochemical oxidation*: oxidation of a solute by passing a direct electrical current through its solution (e.g. chlorine is produced industrially by the electrochemical oxidation of the chloride ion)

*Ilmenite structure*: the structure of the mineral  $\text{FeTiO}_3$

*Metathetical reaction*: a common type of reaction, also known as a double decomposition reaction, in which the anions and cations of the reactants are interchanged in the products (e.g.  $\text{AX} + \text{BY} \rightleftharpoons \text{AY} + \text{BX}$ )

*Perovskite structure*: the structure of the mineral  $\text{CaTiO}_3$

*Platinum metals*: the six platinum metals are ruthenium, rhodium, palladium, osmium, iridium, and platinum

*Radiolysis*: decomposition of a compound by ionizing radiation such as X- or  $\gamma$ -rays or  $\alpha$ -particles

*Rutile structure*: the structure of the mineral rutile, a form of  $\text{TiO}_2$

*Spinel structure*: the structure of the mineral spinel,  $\text{MgAl}_2\text{O}_4$

*Zone refining*: a modern method of refining where a narrow ring furnace melts a thin disk in a vertical rod of impure material under an inert atmosphere. Impurities are more soluble in the melt, and as the ring furnace traverses the rod the impurities are swept to the end for eventual discard. The process may be repeated until the desired degree of purity has been achieved

## Abbreviations

cyclen = 1,4,7,10-tetraazacyclododecane;  $\text{C}_8\text{H}_{12}\text{N}_4$ ;  
dmppe = 1,2-bis[methyl(phenyl)phosphino]ethane; MePhP  
( $\text{CH}_2$ )<sub>2</sub>PMePh; dpav = (Z)-1,2-bis(diphenylarsino)ethylene;  
 $\text{Ph}_2\text{AsCH}=\text{CHAsPh}_2$ ; dppe = 1,2-bis(diphenylphosphino)-  
ethane;  $\text{Ph}_2\text{PCH}_2\text{CH}_2\text{PPh}_2$ ; dppm = *bis*(diphenylphosphino)-  
methane;  $\text{Ph}_2\text{PCH}_2\text{PPh}_2$ ; dppp = 1,3-bis(diphenylphosphino)-  
propane  $\text{Ph}_2\text{P}(\text{CH}_2)_3\text{PPh}_2$ ; dppv = (Z)-1,2-bis(diphenylphos-  
phino)ethylene;  $\text{Ph}_2\text{PCH}=\text{CHPPh}_2$ ; pz = pyrazolyl;  $\Re$  =  
cross-linked polystyrene resin;  $\text{res}^+$  = cross-linked polysty-  
rene anion-exchange resin; tacn = 1,4,7-triazacyclononane;  
 $\text{C}_6\text{H}_{15}\text{N}_3$ ; taud = 1,4,8,11-tetraazaundecane;  $\text{C}_7\text{H}_{20}\text{N}_4$ .

## 1 INTRODUCTION

Rhodium, a relatively rare and expensive metal, is hard, lustrous, high melting, and difficult to work. It is also resistant to chemical attack and its nobility is reflected both in the small number of binary compounds it forms and the ease with which several of these revert to the element.

The main application of rhodium is the production of catalytic alloys with other platinum metals. These alloys are used to reduce the emission of pollutants from automobile exhausts and to catalyze the formation of nitric acid from ammonia.

Despite its few binary compounds, the element gives rise to many complexes. Table 1 indicates the diversity of complexes formed. Several low oxidation state complexes of the element are important homogeneous catalysts, particularly in the oligomerization, isomerization, *Hydrogenation*, *Hydroformylation*, *Hydroboration*, or *Hydrosilation* of alkenes. Iodorhodium complexes catalyze the industrial-scale carbonylation of methanol to acetic acid.

Rhodium compounds are somewhat toxic and have been used in oncological chemotherapy, but they are less effective than platinum complexes. The expense and rarity of rhodium means that it is rarely a significant pollution hazard, particularly as it is of low inherent toxicity. The occupational exposure limit to dust is  $1\text{mgm}^{-3}$  and the  $\text{LD}_{50}$  for oral ingestion is  $200\text{mg kg}^{-1}$  for several species. At these levels, rhodium and its compounds exhibit weak carcinogenicity and adverse reproductive effects have been observed.<sup>1</sup> Nevertheless, rhodium dust and water-soluble rhodium compounds are now found at roadsides as a result of erosion of automobile emission control catalysts.

The inorganic chemistry of rhodium is concerned principally with the complexes in which the element exhibits the oxidation states of I, II, or III, of which  $\text{Rh}^{\text{III}}$  is most common. Oxidation states of  $-I$ , 0, IV, and V are rare.

**Table 1** Representative rhodium complexes

| Oxidation state | $d^n$    | Typical ligands                     | Examples                                               | Geometry                   | Comments   |
|-----------------|----------|-------------------------------------|--------------------------------------------------------|----------------------------|------------|
| –I              | $d^{10}$ | PF <sub>3</sub>                     | [Rh(PF <sub>3</sub> ) <sub>4</sub> ]                   | Tetrahedral                | Rare       |

<sup>a</sup>Distorted. <sup>b</sup>Octahedrally coordinated rhodium.

Rhodium(III) complexes typically contain ammine, halo, or aqua ligands, or the important bidentate ligands 1,2-diaminoethane (en), oxalato, or pentane-2,4-dionato (acac) and are invariably octahedral. Their wide variety is in part a reflection of the slow reactions, which take place at the low-spin  $d^6$  centers, which allow many intermediates, and geometrical or chiral isomers, to be isolated. It is fairly difficult to oxidize rhodium(III) complexes, but they may be reduced to rhodium(I) species in the presence of suitable ligands. However, there is little current work being carried out on the classical rhodium(III) complexes and even less on the higher oxidation states.

The +1 oxidation state has gained importance in the 40 years since its catalytic properties were discovered (see *Rhodium: Organometallic Chemistry*). All isolable Rh<sup>I</sup> complexes contain at least one  $\pi$ -Acid Ligand, which serves to protect the complexes against aerial oxidation or disproportionation. Reaction of Rh<sup>I</sup>L<sub>4</sub> with H<sub>2</sub>, HCl, MeI, or Cl<sub>2</sub> (= XY) often occurs via an *Oxidative Addition* reaction, to give rise to Rh<sup>III</sup>L<sub>4</sub>XY. Only powerful reducing agents such as potassium amalgam are capable of reducing rhodium(I) complexes.

Dimeric carboxylato complexes comprise virtually all the examples of rhodium(II) complexes. These species, of general formula [Rh(O<sub>2</sub>CR)<sub>2</sub>L]<sub>2</sub>, adopt the lantern structure. Four carboxylato ligands bridge the two rhodium atoms; these bridges are supplemented by a single rhodium–rhodium bond. The neutral ligands take up the axial positions to complete the octahedral coordination around the rhodium(II) ion. Apart from metathetical reactions involving either carboxylate or axial ligands, the structure is quite stable and the complexes are neither readily oxidized nor reduced.

As noted above, the other oxidation states are not well represented; the –1 and zero oxidation states are exemplified by [Rh(PF<sub>3</sub>)<sub>4</sub>]<sup>–</sup> and the very similar [Rh<sub>2</sub>(PF<sub>3</sub>)<sub>8</sub>], respectively.

Apart from a few ill-defined oxo species, octahedral hexafluororhodates comprise the bulk of the rhodium(IV) and –(V) complexes isolated.

The key reviews of the inorganic chemistry of rhodium and its complexes are now over a decade old.<sup>2,3</sup> With the possible exception of Griffith's book,<sup>4</sup> earlier reviews usually predate the discovery and application of the important low oxidation state complexes. The reader is referred to these<sup>2–4</sup> for more detailed coverage and references.

## 2 THE ELEMENT AND ITS BINARY COMPOUNDS

### 2.1 Occurrence and Applications

Rhodium occurs only to the extent of 10<sup>–9</sup>% in the earth's crust. Fortunately, it is not evenly distributed, but is found, alloyed with the other platinum metals, to the extent of a few ppm (several grams per tonne) in its ores. The principal locations of these ore bodies are in the Urals near Ekaterinburg (the earliest commercial source) and in the Merensky reef near Pretoria in the Republic of South Africa. The latter is the major source today. Minor sources are found in North America and Zimbabwe. Many platinum metal resources, such as that at Sudbury in Ontario, contain very little rhodium. Various other minor sources are known, and in fact the element was first isolated by Wollaston in 1804 from impure platinum of South American origin.

Rhodium is separated from the other platinum metals either by classical chemical methods or, more recently, by solvent extraction. The latter has the advantage of a more rapid separation, which is financially advantageous with such expensive materials.

The world's supply of rhodium is in approximate balance with demand with erratic releases onto the world market from Russia being counterbalanced by national and industrial stockpiles. These fluctuations in availability are reflected in the spot price, which fell from US\$64 g<sup>-1</sup> at the millennium to US\$17 g<sup>-1</sup> by 2001. The current price in 2004 is US\$26 g<sup>-1</sup>. Of the 2002 world production of 19.0 tonnes and recovered scrap from automobile catalysts of 3.1 tonnes, over 80% was used as rhodium alloy catalysts for automobile emission reduction. The rhodium component is vital in controlling NO<sub>x</sub> emissions and looks set to increase in order to meet higher emission control standards.

Gauzes made from a similar alloy catalyze the oxidation of ammonia to nitric acid and represent the second most important application of the metal. Rhodium dies are used in the drawing of glass fibers. Each of these applications uses about 7% of annual metal production. The traditional rhodium/platinum thermocouple or furnace winding applications or electroplating other metals to increase their tarnish resistance or decrease their electrical contact resistance now account for merely 1% of the supply. Rhodium targets in the X-ray tube of X-ray fluorescence spectrometers are probably responsible for erroneous reports of rhodium in archeological samples. Erosion of catalytic gauzes and of thermocouples at high temperatures results in substantial irrecoverable losses. Nevertheless, rhodium is routinely recovered from virtually all materials.

Rhodium compounds and complexes are also commercially important catalysts. The hydroformylation of propene to butanal (a precursor of *bis*(2-ethylhexyl) phthalate, the PVC plasticizer) is catalyzed by hydridocarbonylrhodium(I) complexes. Iodo(carbonyl)rhodium(I) species catalyze the production of acetic acid from methanol. In the fine chemical industry, rhodium complexes with chiral ligands catalyze the production of L-DOPA, used in the treatment of Parkinson's disease. Rhodium(II) carboxylates are increasingly important as catalysts in the synthesis of cyclopropyl compounds from diazo compounds.<sup>5</sup> Many of the products are used as synthetic, pyrethroid insecticides. Hexacyanorhodate(III) salts are used to dope silver halides in photographic emulsions to reduce grain size and improve gradation.

There is little doubt that the catalytic properties of low-valent rhodium compounds have provided the driving force for the rapid expansion of interest in rhodium chemistry over the last four decades.

## 2.2 The Element

Rhodium was named by Wollaston after its rose colored salts. The hard, silvery, lustrous metal has a specific gravity of 12.41 and crystallizes in the face-centered cubic system ( $a = 3.803 \text{ \AA}$ ). Modern work implies that there is no change in structure up to the melting point of 1960–1970 °C. Despite this structure, it is difficult to cold work and the rate of work

hardening is high, although less so than for either osmium or iridium. It is best worked at 1200 °C.

Modern values for its physical properties are the more reliable since rhodium is difficult to obtain in a highly pure state because of reactions with refractory containers at or near its melting point. The purest samples have been obtained by zone refining. The differing standards of purity can be seen in the range of boiling points (3700–4500 °C) quoted.

Numerous isotopes of rhodium are known, but only <sup>103</sup>Rh is stable. The short half-lives of the remainder mean that few radiochemical applications exist. The heavy isotopes of the element feature among the fission products of uranium and the transuranic elements; they can also be made by neutron irradiation. Light isotopes result from  $\alpha$ -bombardment of the metal, and those of high neutron deficiency from bombardment by very heavy ions.

The atomic mass of the single stable isotope is 102.9055. This has a nuclear spin of 1/2, which has proved invaluable in the NMR spectrometry of its diamagnetic complexes.

The *Ground-State* electronic configuration is [Kr]4d<sup>8</sup>5s<sup>1</sup>. The first, second, and third ionization energies are 7.46, 18.1, and 31.1 eV, respectively.

The massive metal is inert, but very finely divided forms are more reactive, absorbing large quantities of either CO or H<sub>2</sub>. While rhodium black or rhodium sponge dissolves in aqua regia or aqueous chlorine under pressure, larger pieces must be fused with sodium hydrogen sulfate to effect dissolution.

At 600 °C the metal reacts with oxygen to form Rh<sub>2</sub>O<sub>3</sub>, and with chlorine at 300 °C to form RhCl<sub>3</sub>. The reaction is reversed at 318 °C without lower chlorides being formed.<sup>6</sup> Tri-, tetra-, penta-, or hexafluorides are formed by allowing the metal to react with fluorine under suitable conditions. Hexafluororhodate result from the action of fluorine in admixture with either oxygen or nitrosyl fluoride upon the metal (Scheme 1).

Scheme 1

Iodine vapor attacks the metal above 400 °C to form  $\text{RhI}_3$ . However, bromine gives an impure product. Pure  $\text{RhBr}_3$  may be obtained by first allowing the metal to react with an  $\text{HBr}/\text{Br}_2$  mixture and then brominating the first product at 400 °C.

### 2.3 Binary Compounds

The sesquioxide ( $\text{Rh}_2\text{O}_3$ ) adopts the corundum structure at low temperatures and the perovskite structure at high temperatures. The latter form is usually obtained by heating the element or various compounds at 900–1000 °C. Prolonged heating of  $\text{Rh}(\text{NO}_3)_3$  at 730 °C yields the low-temperature form.

If the sesquioxide is heated with oxygen under pressure, a dioxide is formed that has the rutile structure. Further heating causes reversion to the lower oxide, (equation 1).

Various ‘rhodates’ can be prepared by fusing  $\text{Rh}_2\text{O}_3$  and other oxides or carbonates. The alkali metal compounds are of general formula  $\text{M}^{\text{I}}\text{RhO}_2$  ( $\text{M}^{\text{I}} = \text{Li}, \text{Na}, \text{K}$ ). Spinels,  $\text{M}^{\text{II}}\text{Rh}_2\text{O}_4$  ( $\text{M}^{\text{II}} = \text{Be}, \text{Mg}, \text{Zn}, \text{Cd}, \text{Mn}$ ), can be made

similarly, but this structure is not adopted by the alkaline-earth compounds, which are less well defined and of lower stability. Indium, yttrium, and lanthanoid rhodates,  $\text{M}^{\text{III}}\text{RhO}_3$ , have the perovskite structure, but  $\text{FeRhO}_3$  has the ilmenite structure. Niobium or tantalum rhodates have the rutile structure.

Rhodium(III) hydroxide can be prepared by carefully treating aqueous rhodium trichloride with sodium hydroxide. A purer product can be obtained by dissolving the impure hydroxide in chloric(VII) acid and then reprecipitating the lemon-yellow hydroxide with alkali. The hydroxide is an important source of hydrated binary compounds of rhodium (Scheme 2).

The rhodium/sulfur system is complex and the best defined sulfide is the black  $\text{Rh}_2\text{S}_3$ . This compound can be prepared by heating rhodium and sulfur and subliming the product at 1100 °C.

Similar complexities are found in the  $\text{Rh}/\text{Z}$  ( $\text{Z} = \text{P}, \text{As}$ ) systems, where the  $\text{RhZ}_3$  phases have been found to crystallize with the cobalt triarsenide structure.

As we saw in Section 2.2, the halides are usually prepared by direct interaction of the elements. All four trihalides are known, together with the tetra-, penta-, and hexafluorides. No lower, binary halides are known.

The anhydrous trichloride, obtained by direct combination of the elements is of little use as a starting material for

Scheme 2

the preparation of other rhodium compounds since it is insoluble. To obtain a more synthetically useful trichloride, finely divided rhodium is ground with NaCl and the mixture chlorinated at 550 °C. Leaching the product with water yields  $\text{Na}_2[\text{RhCl}_5(\text{H}_2\text{O})]$  (equation 2), from which  $\text{Rh}(\text{OH})_3$  may be precipitated by careful addition of alkali. Dissolution of the hydroxide in the minimum quantity of 12 M HCl produces a dark red material approximating to  $\text{RhCl}_3 \cdot 3\text{H}_2\text{O}$  upon evaporation to dryness. This is the source of nearly all rhodium compounds and complexes (Scheme 3). Additionally, it reacts with CO or alkenes to provide the starting materials for a host of organometallic compounds.

### 3 THE LOWER OXIDATION STATES

Apart from the many carbonyls, very few complexes exist in the lowest oxidation state Rh–I, and its chemistry is essentially that of the tetrahedral anion  $[\text{Rh}(\text{PF}_3)_4]^-$ . This ligand also gives rise to a rare, authentic example of a noncarbonyl rhodium(0) complex. Orange–red, dimeric  $[\text{Rh}_2(\text{PF}_3)_8]$  contains a rhodium–rhodium bond and has trigonal bipyramidal geometry around each metal atom. It can be

reduced to  $[\text{Rh}(\text{PF}_3)_4]^-$ , which is isoelectronic with tetrahedral  $[\text{Co}(\text{CO})_4]^-$ . The  $\text{PF}_2\text{NMe}_2$  analog of the anionic complex is known. Reports of (triphenylphosphine)rhodium(0) complexes should be treated with caution, although  $[\text{Rh}(\text{dppe})_2]$  can be generated electrochemically. Some reactions of these complexes are shown in Scheme 4. Their characteristic property is their ability to form bonds between rhodium and the Group 14 elements.

### 4 RHODIUM(I) COMPLEXES

The outstanding feature of rhodium(I) chemistry is the general tendency to prefer four coordination to five. Very few five-coordinate, 18-electron complexes of general formula  $[\text{RhXL}_4]$  or  $[\text{RhL}_5]\text{X}$  have been prepared. The vast majority of rhodium(I) complexes are four-coordinate, 16-electron species. Some are important homogeneous catalysts for a variety of processes including hydrogenation, hydroformylation, homologation, hydrosilation, hydroboration, isomerization, or decarbonylation. The complexes are aided in their catalytic activity by their facile oxidation to rhodium(III) species which in turn undergo *Reductive Elimination* reactions, thus closing the catalytic cycles. Their potential catalytic applications have led to many new rhodium(I) complexes being prepared over the last 25 years.

Scheme 3

Scheme 4

Stable rhodium(I) complexes usually require the presence of at least one  $\pi$ -acid ligand. The presence of bulky  $\pi$ -acid ligands tends to lead to coordinative unsaturation by ligand dissociation, which can enhance the catalytic activity. Tertiary phosphines meet both these requirements and have the added advantage of conferring solubility in organic solvents.

Although most rhodium(I) complexes in this section contain tertiary phosphines, there is an extensive chemistry of rhodium(I) with alkene or carbonyl ligands.

Anionic complexes are rare: there are a few containing  $\text{PF}_3$  ligands and still fewer with  $\text{PPh}_3$  ligands, and  $\text{SnCl}_3^-$  forms the dimeric complex  $[\text{RhCl}(\text{SnCl}_3)_2]_2^{4-}$ .

#### 4.1 Tricoordinate Complexes

All the isolable tricoordinate complexes such as  $[\text{RhX}(\text{PCy}_3)_2]$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{I}, \text{N}_3$ ), prepared via metathetical reactions of  $[\text{RhF}(\text{cod})]_2$ , contain very large tertiary phosphine ligands. These complexes resemble transient intermediates in catalytic cycles. Triphenylphosphine complexes containing

the large anionic ligands  $\text{N}(\text{SiMe}_3)_2$  and  $\text{N}=\text{C}(\text{CF}_3)_2$  are also known.

The 14-electron complexes are highly reactive and decompose even when stored in an inert atmosphere. They readily bind an additional small ligand. In particular, they react with dinitrogen under mild conditions. However, the dinitrogen ligand is easily lost and this property has been exploited in the preparation of other tricoordinate complexes (equations 3–5).

There are several salts containing the  $[\text{Rh}(\text{PPh}_3)_3]^+$  cation, such as the perchlorate, which can be obtained from

[RhCl(PPh<sub>3</sub>)<sub>3</sub>] and TiClO<sub>4</sub> (equation 6). Another can be prepared similarly from Ti[nido-7-{1-*closo*-1,2-C<sub>2</sub>B<sub>10</sub>H<sub>11</sub>}-7,8-C<sub>2</sub>B<sub>9</sub>H<sub>11</sub>]. The crystal structures of the above complexes have been determined and both contain distorted T-shaped cations. The Rh–P bonds in the dicarbaborane complex are the longer.

The fluorocarbon acids H<sub>2</sub>C(SO<sub>2</sub>CF<sub>3</sub>)<sub>2</sub>, PhCH(SO<sub>2</sub>CF<sub>3</sub>)<sub>2</sub>, HN(SO<sub>2</sub>CF<sub>3</sub>)<sub>2</sub>, H<sub>2</sub>C(SO<sub>2</sub>C<sub>8</sub>F<sub>17</sub>)<sub>2</sub>, or C<sub>8</sub>F<sub>7</sub>SO<sub>3</sub>H also yield the appropriate [Rh(PPh<sub>3</sub>)<sub>3</sub>]X salt when they react with hydridotetrakis(triphenylphosphine)rhodium(I). The stereochemically nonrigid cation readily coordinates an additional ligand.

## 4.2 Four-coordinate Complexes

This is by far the most populous subgroup of rhodium(I) complexes. The vast majority have the general formula [RhXL<sub>3</sub>], but two minor types also exist. The first contains a bidentate acido ligand; the second has bridging acido ligands. The complexes of bidentate acido ligands usually have rhodium bound to the two oxygen or sulfur atoms of the ligand, although some complexes of monothioanions are known where these ligands bind additionally through oxygen, nitrogen, or phosphorus. The complexes may be prepared either by cleaving bridged complexes (with or without bridge metathesis) or, more usually, by expelling the acido ligand and one neutral ligand from one of the numerous [RhXL<sub>3</sub>] complexes (equations 7–10).

There are many examples of dimeric complexes containing bridging halo ligands. Phosphorus ligands of high  $\pi$ -acidity tend to form complexes of this type. Their presence so lowers the electron density on the metal that a second, weakly nucleophilic, halo ligand is coordinated. Ligands of lower  $\pi$ -acidity tend to cleave the bridged starting materials, particularly when present in excess. Dimeric alkene or carbonyl complexes are frequently used as the starting materials to prepare this type of complex, in which case the organo ligands are displaced in the following order: ethylene > cycloocta-1,5-diene > carbonyl. This order also reflects the variety of complexes that can be prepared from

each precursor (equations 11–13).

When [RhH(PPh<sub>3</sub>)<sub>4</sub>] reacts with 4-methoxyacetophenoneanilide in dioxane, orange crystals of [Rh(OH)(PPh<sub>3</sub>)<sub>2</sub>]<sub>2</sub> can be isolated. The anionic complex [RhCl(SnCl<sub>3</sub>)<sub>2</sub>]<sub>2</sub><sup>4-</sup> can be prepared from tin(II) chloride and RhCl<sub>3</sub>·3H<sub>2</sub>O. It is also possible to prepare this type of complex starting from [RhXL<sub>3</sub>] complexes, since the dimeric complexes are much less soluble than the monomers. This lower solubility may also assist the preferential isolation of dimers when hydrated rhodium trichloride reacts with certain tertiary phosphines in ethanolic solution. The halo complexes can serve as the starting materials for the preparation of many other rhodium(I) complexes (Scheme 5).

The structure of several dimers has been confirmed by X-ray crystallography. Unlike [RhCl(CO)<sub>2</sub>]<sub>2</sub>, they are not strongly puckered at the bridge; indeed, the central RhO<sub>2</sub>Rh group of [Rh(OH)(PPh<sub>3</sub>)<sub>2</sub>]<sub>2</sub> is planar,<sup>6</sup> as is the RhCl<sub>2</sub>Rh core of [RhCl(PPh<sub>3</sub>)<sub>2</sub>]<sub>2</sub>·MeCO<sub>2</sub>Et.

Halo-bridged, dimeric complexes containing bidentate neutral ligands may also be prepared, usually by displacement of organo ligands from dimeric complexes either by the bidentate ligand itself (equation 14) or by hydrogenation of a diene complex (equation 15). There is one instance of rhodium trichloride being reduced to a complex of this type.

The [RhXL<sub>3</sub>] species are easily the most important rhodium(I) complexes because of the exceptional catalytic

Scheme 5

properties of *Wilkinson's Catalyst*,  $[\text{RhCl}(\text{PPh}_3)_3]$ , the first successful homogeneous hydrogenation catalyst for alkenes and alkynes. It was later shown to be effective for hydrosilation and decarbonylation reactions.<sup>7</sup>

Of the many different preparative methods known, the standard preparation of  $[\text{RhCl}(\text{PPh}_3)_3]$  is not of wide applicability to other phosphines (equation 16). The best general method for  $\text{RhX}(\text{QR}_3)$  ( $\text{Q} = \text{P}, \text{As}, \text{Sb}$ ) is by displacement of alkene ligands from dimeric rhodium(I) complexes (equation 17). This method also avoids using rare and expensive tertiary phosphines as mere reductants.

( $\text{L} = \text{C}_2\text{H}_4$ ;  $\text{L}' = \text{PPh}_3$ ,  $\text{P}(4\text{-C}_6\text{H}_4\text{OMe})_3$ ,  $\text{P}(4\text{-C}_6\text{H}_4\text{F})_3$ ,  $\text{P}(4\text{-C}_6\text{H}_4\text{Me})_3$ ,  $\text{PPhPh}_2$ ,  $\text{PPh}_2(\text{CH}_2\text{CH}_2\text{SiCl}_3)$ ,  $\text{PPh}_2\text{Me}$ ,  $\text{PPh}_2\text{Et}$ ,  $\text{PPh}_2(\text{C}_8\text{H}_{16}\text{SiCl}_3)$ ,  $\text{PPh}(\text{C}_4\text{H}_8\text{NO})_2$ ,  $\text{PPh}(\text{C}_5\text{H}_{10}\text{N}_2)$ , **3**, **4**,  $\text{PF}_2\text{NMe}_2$ ,  $\text{AsEtPH}_2$ ,  $\text{SPPH}_3$ ;

$\text{L} = \text{C}_8\text{H}_{14}$ ,  $\text{L}' = \text{PF}(\text{NMe}_2)_2$ ,  $\text{P}(4\text{-C}_6\text{H}_4\text{OMe})_3$ ,  $\text{P}(4\text{-C}_6\text{H}_4\text{Cl})_3$ ) (17)

In addition to being a powerful and versatile catalyst,  $[\text{RhCl}(\text{PPh}_3)_3]$  is also the starting point for the preparation

of numerous analogs that can be obtained by metathetical reactions. Schemes 6 and 7 show some replacement reactions of the chloro and triphenylphosphine ligands. Despite the  $4d^8$  electronic configuration, these rhodium(I) complexes are seldom exactly square planar.

Tetrahydroborate or other hydridic anions produce  $[\text{RhH}(\text{PPh}_3)_3]$ , widely used by Robinson's group as the starting point for the preparation of carboxylato and other complexes (equation 18). The IR spectra of  $[\text{Rh}(\text{O}_2\text{CR})(\text{PPh}_3)_3]$  show that the carboxylate is monodentate and therefore Rh is four-coordinate; this has been confirmed by X-ray crystallography for the benzoate.

When neutral ligands replace  $\text{PPh}_3$  in  $[\text{RhCl}(\text{PPh}_3)_3]$ , the incoming ligand usually replaces the triphenylphosphine ligand trans to the chloro ligand (Scheme 7). Several of the complexes which can be prepared from  $[\text{RhCl}(\text{PPh}_3)_3]$  exhibit interesting structures, few more so than the *trans*- $[\text{RhCl}(\text{PPh}_3)_2(\text{P}_4)]$  complex (**5**), which contains an  $\eta^2$ -tetrahedral  $\text{P}_4$  ligand.

### Scheme 6

The  $\text{PX}=\text{C}(\text{SiMe}_3)_2$  ligands ( $\text{X} = \text{F}, \text{Cl}$ ) form  $\eta^1$ -complexes upon reaction with  $[\text{RhCl}(\text{PPh}_3)_3]$  in toluene solution. This contrasts with their reactions with  $d^{10} \text{Ni}^0$  or  $\text{Pt}^0$  species, where both oxidative addition and  $\eta^2$ -coordination may occur.

Another noteworthy species is  $[\text{Rh}(\text{PPh}_3)_3\text{MeCN}]^+$ , which can be prepared from  $[\text{Rh}_2(\text{O}_2\text{CMe})_2(\text{MeCN})_6][\text{BF}_4]_2$  (equation 19). Although MeCN is normally a good leaving group, it is retained in some reactions (equation 20).

Replacement of  $\text{PPh}_3$  by other tertiary phosphines can give important catalysts. Water-soluble analogs of  $[\text{RhCl}(\text{PPh}_3)_3]$  can be prepared by replacing all three  $\text{PPh}_3$  ligands by  $\text{Na}[\text{PPh}_2(3\text{-C}_6\text{H}_4\text{SO}_3)_3]$  or  $\text{Na}_3[\text{P}(3\text{-C}_6\text{H}_4\text{SO}_3)_3] \cdot x\text{H}_2\text{O}$ . These complexes find application in the hydrogenation of biologically important substrates, and also exhibit antitumor

activity. One major problem in homogeneous catalysis is separating the catalyst from the product. This can be overcome by preparing a heterogenized catalyst, which may be achieved by binding a  $\text{RhCl}(\text{PPh}_3)_2$  residue to a  $-\text{PPh}_2$  group attached to a macromolecular support. Typical supports have included cross-linked polystyrene resins or silica. A recent development is the preparation of complexes containing fluorinated tertiary phosphine ligands for use in biphasic catalytic systems.

The mixed anhydrides of diphenylphosphinous acid and heavily substituted alkenoic acids displace one  $\text{PPh}_3$  ligand from  $[\text{RhCl}(\text{PPh}_3)_3]$  to form a complex where the anhydride is coordinated through phosphorus. If these products are treated with thallium(I) or silver(I) salts, the anhydride coordinates additionally through the carbonyl oxygen and the chloro ligand is displaced.

There are relatively few complexes of the stoichiometry  $[\text{RhL}_4]\text{X}$ . Most of these contain small tertiary phosphines and anions of low coordinating power. The complexes of secondary phosphines are much in evidence and tertiary phosphite complexes are also known.

Much studied recently,  $[\text{Rh}(\text{PMe}_3)_4]\text{Cl}$  owes much of its reactivity to the facile loss of a  $\text{PMe}_3$  ligand. The other

Scheme 7

complexes are much less reactive (equations 21–23).

The complexes are usually prepared by displacing ligands from other rhodium(I) complexes. Complexes containing two bidentate ligands may be prepared similarly. Additionally, simultaneous anion metathesis and ligand displacement may

be employed when complexes containing poorly coordinating anions are sought.

There are numerous  $[\text{Rh}(\text{LL})_2]\text{X}$  complexes. Probably the most important of these are those complexes containing two chiral bidentate ligands (equations 24–26). The best known, containing the chiral ligand diop (**6**), have been widely employed in homogeneous asymmetric synthesis, where they have proved to be of increasing importance in the pharmaceutical industry (*see Asymmetric Synthesis by Homogeneous Catalysis*).

The reactions of [Rh(dppe)<sub>2</sub>]Cl (Scheme 8) show that the major reaction is anion metathesis.

Pentacoordinate complexes adopt two stoichiometries. The neutral hydrido complexes are probably more numerous than the [RhL<sub>5</sub>]X salts. The structures of the hydrido complexes are

difficult to establish. X-ray crystallographic studies seldom locate the hydrido ligand and its position must be inferred from the disposition of the other ligands. In solution, <sup>1</sup>H NMR studies show the high-field line to be split into a weak multiplet by both rhodium and the phosphorus atoms present. On the evidence available, most complexes appear to have the monocapped tetrahedron structure. The phosphorus ligands found in the hydrido complexes include tertiary phosphines, ditertiary phosphines, and trialkyl phosphites. Chloro complexes are only known for small ligands of high π-acidity such as PF<sub>2</sub>(NMe<sub>2</sub>). Trialkyl phosphites appear to be the only ligands capable of forming [RhL<sub>5</sub>]<sup>+</sup> cations. This may again be due to their high π-acidity and their small *Cone Angles*. All the isolated complexes contain the large [BPh<sub>4</sub>]<sup>−</sup> counter ion, suggesting that the cations are unstable in the presence of small, polarizing anions. The white complexes can be prepared by displacement of alkene ligands from rhodium(I) complexes in the presence of [BPh<sub>4</sub>]<sup>−</sup> ions. As might be expected, the trialkyl phosphite ligands are easily lost.

Scheme 8

## 5 RHODIUM(II) COMPLEXES

There are three types of rhodium(II) complex. By far the most common are the dimeric carboxylatorrhodium(II) species. Octahedral complexes may also be generated by the radiolysis of aqueous solutions of classic rhodium(III) complexes. Square-planar complexes containing bulky tertiary phosphine ligands can be produced by careful reduction of hydrated rhodium trichloride. The chemistry of rhodium(II) differs very considerably from the well-known monomeric octahedral or tetrahedral cobalt(II) species because cobalt(II) complexes are high-spin  $d^7$  species while rhodium(II) complexes are all low spin. No spin reorientation is required upon oxidation to rhodium(III), so monomeric rhodium(II) complexes are excellent reducing agents.

### 5.1 Monomeric Complexes

The complexes generated by photolysis or radiolysis of rhodium(III) precursors usually have very short lifetimes. The ammine complexes derived from radiolysis of aqueous solutions of  $[\text{RhCl}(\text{NH}_3)_5]^{2+}$  are easily oxidized. The radiolysis of solutions of  $[\text{Rh}(\text{bipy})_3]^{3+}$  generates the corresponding rhodium(II) complex, which undergoes disproportionation to rhodium(III) and rhodium(I) complexes, the latter containing only two bipy ligands (equation 27).

The best test for monomeric rhodium(II) complexes is their paramagnetism since both rhodium(I) and rhodium(III) complexes are diamagnetic. These complexes owe their stability either to the large size of the ligands or their electronic properties. Bulky ligands include porphyrins and tertiary phosphines. Typical tertiary phosphine ligands include tris(2-tolyl)phosphine, di-*t*-butyl(alkyl)phosphines, or tris(cyclohexyl)phosphine. These ligands reduce hydrated rhodium trichloride to the rhodium(II) complexes in ethanol at low temperatures (equation 28), rather than the reflux temperature required to bring about reduction to rhodium(I). Although no authentic rhodium(II) complexes containing tertiary arsines are known, tris(2-tolyl)stibine forms diamagnetic  $[\text{RhX}_2\{\text{Sb}(\text{C}_6\text{H}_4\text{Me})_3\}]$  complexes when it reacts with rhodium(III) halides. A dimeric structure has been proposed to account for the diamagnetism.

Nonplanar or highly substituted Schiff bases also confer steric protection upon their rhodium(II) complexes. By contrast relatively simple thio ligands such as

*N,N*-dialkyldithiocarbamates produce stable, square-planar rhodium(II) complexes of the type  $[\text{Rh}(\text{S}_2\text{CNR}_2)_2]$  ( $\text{R} = \text{Me}, \text{Et}$ ); similar anionic *bis*(maleonitriledithiolate) are also known. Neutral complexes are formed by the thiol containing amino acids cysteine, methyl cysteine, or penicillamine. It is noteworthy that these paramagnetic  $[\text{Rh}(\text{aminoacid})_2]$  complexes can easily be prepared from dimeric, diamagnetic  $[\text{Rh}(\text{O}_2\text{CMe})_2\text{MeOH}]_2$ .<sup>8</sup>

### 5.2 Dimeric Complexes

The best-known complexes of this type are the carboxylates (7) and their derivatives (8). The four bridging carboxylato ligands are supplemented by a single rhodium–rhodium bond. The bond lengths in the cores of these structures are almost independent of the ligands present. In particular, the Rh–Rh bond length increases by only 0.08 Å upon changing the axial ligand, L, from methanol to  $\text{P}(\text{OMe})_3$  in the acetate complexes. Many other oxo-bridged dimers are known with similar Rh–Rh bond lengths. The principal reaction of the dimers is the substitution of the neutral axial ligands (Scheme 9). The propanoate reacts more rapidly than the acetate, which may partly explain its superior antitumor activity. Many different monodentate ligands can be bound to the axial sites. Oxygen donors, which form blue or green complexes, include water, the lower aliphatic alcohols, dimethyl sulfoxide, and tetrahydrofuran.

Thiols also bind to these sites, as does chloride ion in forming  $[\text{Rh}(\text{O}_2\text{CR})_2\text{Cl}]_2^{2-}$  anionic complexes. Nitrogenous ligands form many complexes, those of ammonia, pyridine, and both primary and secondary amines being well represented. Like the complexes of sulfur ligands, these are red or orange. Diamines also form complexes. Where the diamine geometry is favorable, for example, phenazine (9) or tetramethylphenylenediamine (10), they form polymeric chains of the type  $[-\text{LLRh}(\text{O}_2\text{CR})_4\text{RhLLRh}-]_n$ .

It has recently been shown that 2,2-bipyridine forms the complex (11). The importance of this structure is that it demonstrates the possibility of carboxylatorrhodium(II) complexes acting in the same way as the well-known cisplatin (*cis*- $[\text{PtCl}_2(\text{NH}_3)_2]$ ) in cancer chemotherapy (*see*

Scheme 9

(9)

(10)

**Platinum-based Anticancer Drugs**). The latter disrupts mutant DNA by interstrand attachment to two adjacent guanine bases. Previously, it had been believed that the carboxylato complexes could not bind to DNA in this fashion. This may prompt further investigation of the antitumor activity of the rhodium complexes, which induce fewer harmful side effects than the platinum complexes.

Tertiary phosphines or phosphites may also occupy the axial sites. Their high  $\pi$ -acidity lengthens the Rh–Rh bond, and the colors of their complexes range from red to yellow. Carbonyl, nitrosyl, or isocyanide ligands also lengthen the metal–metal bond. It should be noted that triphenylphosphine does not reduce the carboxylato complexes to rhodium(I) species. Polymeric complexes can be formed by  $\alpha, \omega$ -dinitriles linking the axial sites of two lantern units. Axial  $I_2$  ligands can link  $[Rh(O_2CCF_3)_2]_2$  units without oxidizing them.<sup>9</sup>

The carboxylato ligands also participate in metathetical reactions. These have been exploited to prepare homologous complexes. The carboxylato ligands can be replaced stepwise, and a few mixed carboxylato complexes have been isolated. The carboxylato complexes have been shown to be inefficient alkene hydrogenation catalysts.

Other bidentate ligands can bridge the two rhodium atoms. The complexes of the trifluoroacetamide anion,  $CF_3CNH^-$ , have been widely studied. Two isomeric products (**12**) and (**13**) are formed when the  $[Rh(HNCOCF_3)_2]_2$  complex is allowed to react with 1,10-phenanthroline and  $[NBu_4]Cl$  (equation 29). Of these, only the less symmetric (**12**) undergoes the further reaction with pyridine and  $K[PF_6]$  (equation 30). These species again demonstrate the possible interaction between the dimeric complexes and DNA. However, carboxamide complexes show great promise as chiral cyclopropanation catalysts in the reactions between diazoesters and alkenes.<sup>10</sup> Attempts to fine tune the catalytic properties of the complexes make this a very active research area.

Another class of ligand that forms bridged dimeric complexes includes 6-methyl- or 6-halo-2-oxypyridines. The substituent at the 6-position is essential to discourage axial bonding, particularly when they are prepared via bridge metathesis, although they can be prepared directly from  $RhCl_3 \cdot 3H_2O$ . When a bidentate ligand coordinates through two different donor atoms the four isomers (**14**)–(**17**) are possible. These are designated the 4,0, 3,1, *cis*-2,2, and *trans*-2,2 isomers, respectively. Examples of all these isomers may be prepared from this class of ligand. Additionally, the 6-methyl-2-oxypyridine ligand can form a tetrameric complex when one of the four oxygen atoms increases its coordination number to four to bridge two 3,1-dimeric units.

Despite the ubiquity of bridged species, several examples of dimeric unbridged rhodium(II) complexes are known. Heating  $[Et_3O][BF_4]$  with  $[Rh(O_2CCF_3)_2]_2$  in MeCN forms  $[Rh_2(MeCN)_{10}][BF_4]_4$ . The cation has Rh–Rh linked, staggered square-pyramidal units.<sup>11</sup> The aqua complex  $[(H_2O)_5Rh-Rh(H_2O)_5]^{4+}$  is also known. Several inorganic oxo anions, for example, sulfate, carbonate, hydrogen carbonate, or dihydrogen phosphate, form bridged complexes with the aqua complex (equation 31).

The *bis*(octaethylporphyrin)dirhodium complex is also unbridged. The reduction of  $[Rh(dmg)_2Cl_2]^-$  by tetrahydroborate in the presence of  $PPh_3$  forms the unbridged rhodium(II)

complex  $[\text{Rh}(\text{dmg})_2\text{PPh}_3]_2$  (**18**) (equation 32). This complex has axial  $\text{PPh}_3$  ligands and a very long Rh–Rh bond of 2.936 Å. The parent complex can be prepared by the reaction of  $\text{dmgH}$  and  $[\text{Rh}(\text{O}_2\text{CMe})_2]_2$ .

## 6 RHODIUM(III) COMPLEXES

The extensive chemistry of this oxidation state has two facets. The classical complexes containing  $\sigma$ -bonded ligands have been known for nearly two centuries. At the beginning of the twentieth century, they were widely used by Alfred Werner in his fundamental research into the constitution, stereochemistry, and isomerism of coordination compounds.

However, over the last 60 years a new type of chemistry has emerged. Although the first examples, tertiary arsine complexes, were initially prepared as an extension of classical rhodium(III) chemistry, the newer complexes containing  $\pi$ -bonding ligands have been a consequence of the intense interest in the catalytic properties of rhodium(I) complexes. Examples of these ligands also include tertiary phosphines and stibines, although it is debatable to what extent they act as  $\pi$ -acids when coordinated to rhodium(III).

This historical distinction is paralleled by the widely different chemistries exhibited by the two types of complex. The classical complexes are invariably octahedral and react so slowly that studies of their reactions are of kinetic rather than synthetic interest. They are impervious to both oxidation and reduction in aqueous solution.

On the other hand, rhodium(III) complexes containing  $\pi$ -bonded ligands are often pentacoordinate and undergo very rapid reductive elimination reactions. It is their ability to undergo this reaction that makes possible much of the important catalytic activity exhibited by lower oxidation state rhodium complexes.

### 6.1 Complexes of $\sigma$ -bonding Ligands

A wide range of rhodium(III) complexes contain halo, aqua, ammine diaminoalkane, or dicarboxylato ligands. Rhodium(III) complexes whose net ionic charge varies from +3 to –3 are known. With complexes that react slowly, it is possible to isolate most intermediate complexes in the interconversions of  $[\text{Rh}(\text{H}_2\text{O})_6]^{3+}$  and  $[\text{RhCl}_6]^{3-}$  (Scheme 10). The slow reaction rates of these complexes also allow geometrical isomers to be isolated. Additionally, the *cis*- $[\text{RhX}_2(\text{LL})_2]^+$  and  $[\text{Rh}(\text{LL})_3]^n$  complexes containing bidentate ligands are chiral and may be resolved into their optical isomers.

The complexes of halo or pseudohalo ligands make a convenient starting point for the discussion of those complexes containing monodentate ligands. The hexaiodo complex is unknown, but the other  $[\text{RhX}_6]^{3-}$  complexes ( $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{CN}, \text{SCN}, \text{SeCN}$ ) are all well established. In contrast to rhodium(I) complexes, the  $\text{SCN}^-$  and  $\text{SeCN}^-$  ions are chalcogenide bound. The stable hexafluororhodate(III) complex is low spin, unlike the corresponding  $\text{Co}^{\text{III}}$  complex, which is a rare  $d^6$  high-spin complex and a powerful oxidizing agent. The hexanitrorhodate(III) ion can be prepared from  $[\text{RhCl}_6]^{3-}$  (equation 33). The tripotassium salt, like its cobalt(III) analog, is insoluble in water. Di- and trihalo-bridged species, (**19**) and (**20**) respectively, can be formed from  $[\text{RhCl}_6]^{3-}$  at high temperatures and from  $[\text{RhBr}_6]^{3-}$  in solution.

Aquation is the principal reaction in solution. As can be seen in Scheme 10, the trans labilizing effect of  $\text{Cl}^-$  is greater than that of the aqua ligand. Once the ligands trans to  $\text{Cl}^-$  are replaced by water, *fac*- $[\text{RhCl}_3(\text{H}_2\text{O})_3]$  is inert to further aquation. It has also been found that the chloro ligand trans to water in  $[\text{RhCl}_5(\text{H}_2\text{O})]^{2-}$  has the shortest Rh–Cl bond.

The hexaaqua ion is virtually the sole example of a rhodium(III) ion complexed by six monodentate oxygen ligands. Solutions of this ion are acid due to hydrolysis ( $\text{pK}_a = 3.3$ ). Its principal reaction is anation, but it is difficult to isolate  $[\text{RhX}(\text{H}_2\text{O})_5]^{2+}$  intermediates since the formation of *trans*- $[\text{RhX}_2(\text{H}_2\text{O})_4]^+$  is much more rapid. Hydrated rhodium trichloride, nominally  $\text{RhCl}_3 \cdot 3\text{H}_2\text{O}$ , is a mixture of several aquachloro complexes in which *fac*- and *mer*- $[\text{RhCl}_3(\text{H}_2\text{O})_3]$  predominate. Since  $\text{BaCl}_2$  gives no precipitate

Scheme 10

with  $\text{Rh}_2(\text{SO}_4)_3 \cdot 6\text{H}_2\text{O}$ , it is unlikely that it contains the  $[\text{Rh}(\text{H}_2\text{O})_6]^{3+}$  ion, more recent studies imply that dimeric cationic species are formed in aqueous solution. The only rhodium(III) carboxylate known is the unusual oxotrirhodium complex (**21**). This can be prepared either from silver(I) acetate and aqueous  $\text{RhCl}_3 \cdot 3\text{H}_2\text{O}$  (Scheme 3) or by ozonization of rhodium(II) acetate.

Several dialkyl sulfides form  $[\text{RhX}_3(\text{R}_2\text{S})_3]$  complexes. Some of these have been employed as alkene hydrogenation catalysts; however, they are only weakly active.

The hexamine complex can only be prepared in sealed tube reactions (equation 34), unless the incorporation of the sixth ammine ligand is catalyzed by ethanol. In contrast, the pentaammine complexes are very accessible, and their anation and aquation reactions (Scheme 11) have been exhaustively

studied. However, the exact mechanism of the anation reaction remains in doubt. While an interchange,  $\text{I}$ , mechanism is involved, conflicting arguments have been advanced for  $\text{I}_a$  or  $\text{I}_d$  paths. The aquation reaction is catalyzed by  $\text{Hg}^{2+}$  or  $\text{OH}^-$

### Scheme 11

**Scheme 12**

ions.

The tetraammine complexes also undergo several substitution reactions (Scheme 12). Most of these reactions

involve the trans isomers, possibly because these are less soluble and more easily isolated than the cis isomers. However, they are overshadowed by the more important  $[\text{RhX}_2(\text{N}-\text{N})_2]^+$  analogs (see below). The complex *trans*- $[\text{RhCl}_2\text{py}_4]\text{Cl}$  is an important starting material for other rhodium(III) complexes because of the ease with which the pyridine ligands may be replaced. Its anation

reactions are also a source of other rhodium(III) complexes (Scheme 13).

Both *fac*- and *mer*-triammine complexes have been prepared. Di- and monoammine complexes are neither particularly stable nor important.

Bidentate oxygen ligands form numerous rhodium(III) complexes. Several tris( $\beta$ -diketonato) complexes have been prepared from rhodium(III) nitrate (equation 35). The products are extraordinarily stable. They can be resolved into their optical isomers, and survive nitration and formylation reactions (equations 36 and 37). The tris(oxalato)rhodate(III) ion has also been resolved, but the enantiomers undergo slow racemization. Reaction of this complex with refluxing chloric(VII) acid leads to *cis*-[Rh(ox)<sub>2</sub>(H<sub>2</sub>O)<sub>2</sub>], which can be converted into *cis*- or *trans*-[RhX<sub>2</sub>(ox)<sub>2</sub>]<sup>3-</sup> complexes.

The important [Rh(en)<sub>3</sub>]<sup>3+</sup> ion can be prepared by a variety of reactions (equations 38 and 39). The ion has been resolved and more recently the (-)-enantiomer has been shown to exist in the L configuration. Owing to its inertness, no ligand-substitution reactions have been reported. However, KNH<sub>2</sub> deprotonates the complex and allows its conversion to other species (equation 40). The tris(bipy) and [Rh(phen)<sub>3</sub>]<sup>3+</sup> complexes have also been prepared and

resolved.

Scheme 13

The *bis*(1,2-diaminoethane) complexes are more reactive, and their aquation and anation reactions have been widely studied (Scheme 14). The *cis*-[RhX<sub>2</sub>(en)<sub>2</sub>]<sup>+</sup> ion may be resolved, and (+)-[Rh(ox)(en)<sub>2</sub>]<sup>+</sup> has been assigned the  $\Delta$  configuration. The substitution reactions of the X<sub>2</sub> ligands proceed with retention of configuration.

Unlike the [RhX<sub>2</sub>(en)<sub>2</sub>]<sup>+</sup> ions, which can exist as either *cis* or *trans* isomers, both [RhX<sub>2</sub>(bipy)<sub>2</sub>]<sup>+</sup> and [RhX<sub>2</sub>(phen)<sub>2</sub>]<sup>+</sup> cations and their derivatives are exclusively *cis* (cf. the exclusively *trans*-[RhCl<sub>2</sub>py<sub>4</sub>]<sup>+</sup> ion above). Complexes of rhodium(III) with polydentate nitrogen ligands can also be prepared. Tridentate diethylenetriamine (**22**) forms [Rh(dien)<sub>2</sub>]I<sub>3</sub> when allowed to react with rhodium trichloride in the presence of NaI. The trichloride salt can be obtained by metathesis with AgCl. The reactions of 1,4,7-triazacyclononane inorganic complexes are of current interest (Scheme 15).<sup>12</sup>

The quadridentate ligands trien (**23**), taud (**24**), 1,4,7,10-tetraazacyclododecane, and 1,4,8,11-tetraazacyclotetradecane all form rhodium(III) complexes. Both the cyclic ligands form predominantly *cis*-[RhCl<sub>2</sub>(N<sub>4</sub>)]<sup>+</sup> complexes when their hydrochlorides react with aqueous rhodium trichloride in the presence of a base. All three possible isomers (**25**)–(**27**) of the [RhX<sub>2</sub>(trien)]<sup>+</sup> cation have been characterized. The ligand (**24**) forms *trans*-[RhCl<sub>2</sub>(taud)]<sup>+</sup>, which may be prepared from either rhodium trichloride or *trans*-[RhCl<sub>2</sub>py<sub>4</sub>]<sup>+</sup>. Both *cis* and *trans* products are formed from 1,4,8,11-tetraazacyclotetradecane and RhCl<sub>3</sub>·3H<sub>2</sub>O. Each complex undergoes anation and metathetical reactions, and the *cis* complex can be resolved into its optical isomers. Other macrocyclic tetradentate ligands such as porphyrins or phthalocyanines form complexes where the four nitrogen atoms occupy the four equatorial coordination sites.

## 6.2 Complexes of $\pi$ -bonding Ligands

Although some of these complexes are obtained from rhodium(III) precursors, most arise from oxidative additions to rhodium(I). An indication of the diversity of rhodium(III) complexes that can be obtained from [RhCl(PPh<sub>3</sub>)<sub>3</sub>] is given in Scheme 16. Just as was the case with rhodium(I), there are very few anionic complexes containing  $\pi$ -bonding ligands. The general formula of the anions is [RhX<sub>4</sub>L<sub>2</sub>]<sup>−</sup>. There are also some interesting complexes containing the thioarsine (**28**), in which the ligand occurs in both anion and cation.

The majority of the pentacoordinate cationic complexes contain at least one hydrido ligand, although some are known to contain bulky neutral ligands. The latter may be regarded as the rhodium(III) analogs of the tricoordinate rhodium(I) complexes (see Section 4.1 above), from which most have been prepared by oxidative addition reactions.

The hydrido complexes, in turn, can be regarded as the analogs of the [RhHL<sub>2</sub>] complexes in which coordinative unsaturation is a consequence of the high *trans* effect of the H<sup>−</sup> ligand. They exhibit either trigonal bipyramidal or square pyramidal geometry. The hydrido ligand occupies the apical position in the *bis*(*t*-butyldipropylphosphine) complex (**29**), which can be prepared from RhCl<sub>3</sub>·3H<sub>2</sub>O. More usually the complexes are prepared by oxidative addition of monohydrides to rhodium(I) complexes. Two very important catalyst types can be prepared by adding either a hydrosilane or borane<sup>13</sup> to [RhCl(PPh<sub>3</sub>)<sub>3</sub>]. The hydridocatecholborane derivative catalyzes the hydroboration of alkenes; oxidation and hydrolysis of the resulting boranes produces alcohols.

The numerous [RhHCl(SiX<sub>3</sub>)(PPh<sub>3</sub>)<sub>2</sub>] complexes (**30**) are potent hydrosilation catalysts for alkenes, alkynes, ketones, and other organic substrates containing either an active hydrogen or a multiple bond.<sup>7</sup> Many examples have been isolated in hydrosilation reactions. The complex [RhHCl(SiAr<sub>3</sub>)(PPR<sup>*i*</sup><sub>3</sub>)<sub>2</sub>] is square pyramidal but *mer*-[RhHCl(SiHAr<sub>2</sub>)(PMe<sub>3</sub>)<sub>3</sub>] complexes are formed from [RhCl(PMe<sub>3</sub>)<sub>4</sub>] and SiHAr<sub>3</sub>.<sup>14</sup> Besides being important catalysts, the complexes are also the source

## Scheme 14

Scheme 15

Scheme 16

of many other rhodium complexes (equations 41 and 42). Germeryl analogs are known, but excess  $\text{GeHCl}_3$  converts  $[\text{RhCl}(\text{PPh}_3)_3]$  to the  $[\text{Rh}(\text{GeCl}_3)_6]^{3-}$  anion.

Another important subgroup of monohydrido complexes can be prepared by the oxidative addition of *nido*-heteroborane anions to  $[\text{RhCl}(\text{PPh}_3)_3]$  (Scheme 17). Further, the *closa*-dicarborane complex is the starting material for the preparation of other rhodium(III) borane complexes (Scheme 18). They are also weakly active hydrogenation catalysts.

Scheme 17

Several pentacoordinate monohydrido complexes can add an additional, small, neutral ligand to form complexes of the type  $[\text{RhHX}_2\text{L}_2\text{L}']$ . The dihydrido complexes are conveniently prepared by the oxidative addition of dihydrogen to rhodium(I) complexes dissolved in inert organic solvents. Chlorinated

solvents are unsuitable since the hydrido complexes produced may reduce them with formation of  $\text{HCl}$  and contaminate the product with monohydrido complexes (see Scheme 16). A characteristic stoichiometric reaction of many dihydrides is the addition of a third neutral ligand to form  $[\text{RhH}_2\text{XL}_2\text{L}']$

Scheme 18

complexes (equation 43). However, the principal reaction of the dihydrides is the catalytic reduction of C=C bonds. The hydrido complexes can be characterized by reference to the high-field line in their  $^1\text{H}$  NMR spectra and the presence of a weak band at  $\text{ca. } 2000\text{ cm}^{-1}$  in their IR spectra attributable to  $\nu_{\text{Rh-H}}$ .

Pentacoordinate complexes can also arise from reactions between rhodium(I) complexes and dioxygen. The reactions between the complexes and dioxygen under very slightly different conditions can, however, easily give rise to other products.

Chlorotris(triphenylphosphine)rhodium(I) forms  $[\text{RhCl}(\text{O}_2)(\text{PPh}_3)_n]$  ( $n = 2, 3$ ) or  $[\text{RhCl}(\text{O}_2)(\text{PPh}_3)_2]_2$ . The last complex is six coordinate and has structure (31). Ligand oxidation can also occur. A diagnostic test for the presence of  $\text{O}_2$  ligands is a band at  $870\text{--}900\text{ cm}^{-1}$ , attributable to  $\nu_{\text{O-O}}$ , in the IR spectrum.

Another catalytically important type of pentacoordinate complex has recently been prepared by the oxidative addition of *bis*(benzoborazoles) to  $[\text{RhCl}(\text{PPh}_3)_3]$ . The boryl groups are labile – hence their complexes' ability to catalyze borylation of organic substrates – and can be replaced by other boryl groups (Scheme 19).<sup>13</sup> Trimethyl phosphine

forms  $[\text{RhCl}(\text{BO}_2\text{C}_6\text{H}_4)_2(\text{PMe}_3)_3]$  when allowed to react with  $[\text{RhCl}(\text{BO}_2\text{C}_6\text{H}_4)_2(\text{PPh}_3)_2]$ , but  $\text{PEt}_3$  merely replaces the  $\text{PPh}_3$  ligands to form a trigonal bipyramidal product.

Many complexes that appear to be pentacoordinate are actually six coordinate by virtue of the presence of a bidentate anion or an uncharacteristically bidentate neutral ligand. The former type are exemplified by complexes containing 1,3-diaryltriazenido (32) or disulfur anions. Both examples may be prepared by oxidative addition reactions. Those complexes of uncharacteristically bidentate ligands may be prepared by allowing rhodium(III) halides to react with a stoichiometric deficiency of the ligand. A second neutral ligand may become bidentate when a chloro complex undergoes a metathetical reaction with an anion of low coordinating power or isomerizes in a polar solvent (Scheme 20).

Scheme 19

Scheme 20

Dinuclear complexes can also have the same empirical formulas as pentacoordinate complexes. Their  $^{31}\text{P}$  NMR spectra show that they adopt the noncentrosymmetric structure (33). Monomeric trialkylphosphine complexes are difficult to prepare and attempts at purification often lead to disproportionation (equation 44). The trihalo-bridged dimers adopt structure (34), in which each phosphorus atom is trans to a different chloro bridge.

Despite the high trans effect of the hydride ligand there are also many six-coordinate hydride complexes of general formula  $[\text{RhHX}_2(\text{ZR}_3)_3]$  ( $\text{X}$  = halide;  $\text{Z}$  = P, As). These complexes have two isomeric forms designated  $\alpha$  and  $\beta$  and are shown in structures (35) and (36), respectively. They can

be distinguished by means of IR or NMR spectrometry. The action of bases causes reductive elimination of hydrogen halide and the formation of a rhodium(I) complex (equation 45). Similarly, the  $[\text{RhX}_3\text{L}_3]$  complexes can exist as *fac* or *mer* isomers. The *fac* isomers are formed only by the smallest tertiary phosphines or arsines and are easily outnumbered by the meridional complexes. Virtually no attempts have been made to study the chemical reactions of the *fac* complexes.

There are very few  $[\text{RhX}_2\text{L}_4]\text{X}$  complexes, although numerous analogs containing two bidentate neutral ligands have been prepared (see below). Perhaps the most important are the dioxygen complexes (37), arising from the addition of dioxygen to rhodium(I) complexes. The presence of a peroxy ligand has been confirmed by X-ray crystallography. Dioxygen complexes are well represented and indeed even disulfur analogs have been prepared from cyclo-octasulfur. The dioxygen complexes react with the lower oxides of nonmetals to form complexes containing oxyanions. Complexes containing ditertiary phosphines may be prepared from rhodium(III) halides, by displacing monodentate ligands from rhodium(III) complexes, or by oxidative addition to rhodium(I) complexes (Scheme 21). Strangely, there seem

to be no *tris*(ditertiary phosphine or arsine) analogs of  $[\text{Rh}(\text{en})_3]^{3+}$  or  $[\text{Rh}(\text{bipy})_3]^{3+}$ .

The tridentate ligands (38)–(40) form rhodium(I) complexes. The complexes of the first two ligands readily undergo oxidative addition to form rhodium(III) complexes. The complex  $[\text{RhCl}(\mathbf{38})]$  also adds either  $\text{SO}_2$  or  $\text{BF}_3$  to form pentacoordinate rhodium(I) complexes. The tetradentate ligands (41) ( $\text{Z} = \text{P}, \text{As}$ ) and (42) and the hexadentate ligand (43) form both rhodium(I) and (III) complexes. By contrast, the tri(tertiary arsine) ligand (44) fails to reduce hydrated rhodium trichloride and forms both *fac*- and *mer*-trihalorhodium(III) complexes.

Scheme 21

## 7 THE HIGHER OXIDATION STATES

The number and variety of compounds in oxidation states of four or greater is dramatically lower than for rhodium(III). Essentially only oxo and halo species are formed, and none of these are cationic.

Binary rhodium(IV) compounds are confined to the purple red tetrafluoride and the black dioxide. The hydrated dioxide may be prepared by oxidizing rhodium(III) compounds, either with chlorine or electrochemically. Attempts to dehydrate this material lead to decomposition. No cationic rhodium(IV) complexes have been characterized unambiguously, but both  $[\text{RhCl}_6]^{2-}$  and  $[\text{RhF}_6]^{2-}$  are well established. The alkali metal salts of the hexafluororhodate(IV) ion are all isomorphous with their platinate(IV) analogs.

The hexahalorhodate(IV) complexes are best prepared by oxidizing the solid hexahalorhodate(III) species with the appropriate halogen. The hexafluororhodate ion is relatively easily hydrolyzed, but the hexachloro anion is a powerful oxidizing agent. In water, it disproportionates to chlorine and aquarhodium(III) species. Indeed, the blue species (Claus' blue) formed on oxidation of rhodium(III) species by chlorine, bromate(I), or ozone in aqueous solution have been shown to be peroxorhodium(III) compounds. Thus, only  $\text{Cs}_2[\text{RhCl}_6]$  (obtained by oxidation with  $[\text{Ce}(\text{NO}_3)_6]^{2-}$ ) can be precipitated from aqueous solution before decomposition occurs.<sup>15</sup> The hexachlororhodate(IV) ion is also very rapidly reduced via an *Outer-Sphere Reaction* when allowed to react with the  $[\text{Ru}(\text{phen})_3]^{2+}$  ion. The greater stability of the hexafluoro complex is exemplified by the solid-state preparations of  $[\text{O}_2][\text{RhF}_6]$  and  $[\text{NO}]_2[\text{RhF}_6]$ . All the hexahalorhodate(IV)

complexes are paramagnetic and are presumably low-spin  $d^5$  species.

A number of poorly characterized materials such as  $\text{Na}_2[\text{RhO}_3]$  or  $\text{Sr}_4[\text{RhO}_6]$  have been reported in the literature. However, most of these materials have been found to be contaminated with rhodium(III) species.

Rhodium(V) is even less well represented than rhodium(IV). The only binary compound is the ruby red, tetrameric pentafluoride. The only complex is  $[\text{RhF}_6]^-$ . Bright yellow  $\text{M}^I[\text{RhF}_6]$  salts ( $\text{M}^I = \text{Na}, \text{K}, \text{Rb}, \text{Cs}$ , but not  $\text{Li}$ ) have been prepared by heating  $\text{RhCl}_3$  and  $\text{M}^I\text{Cl}$  in  $\text{IF}_5$  or  $\text{ClF}_5$ . The sodium salt is paramagnetic and contains the low-spin  $d^4$  rhodium(V) ion. Alkaline-earth salts can also be prepared if gaseous  $\text{ClF}_5$  is used as the fluorinating agent. The anions are very moisture sensitive and require strictly anhydrous conditions. Nevertheless, they can be converted to salts of the  $\text{O}_2^+$ ,  $\text{NO}^+$ , or  $[\text{YF}_6]^+$  ( $\text{Y} = \text{Kr}, \text{Xe}$ ) cations. The colors observed in  $[\text{BiO}_3]^-$  oxidations of rhodium(III) salts have been associated with the +5 and even +6 oxidation states, but good evidence is lacking.

## 8 NITROSYL COMPLEXES

Although rhodium forms far fewer *Nitrosyl Complexes* than its neighbor in the *Periodic Table*, ruthenium, over 50 nitrosyl rhodium complexes are known, in addition to some ill-characterized ternary halorhodium nitrosyls. Three main series of complexes exist, with general formulas  $[\text{Rh}(\text{NO})\text{L}_3]$ ,  $[\text{RhX}_2(\text{NO})\text{L}_2]$ , and  $[\text{Rh}(\text{NO})\text{L}_4]\text{X}$ . There are also a few dinitrosyls of the type  $[\text{Rh}(\text{NO})_2\text{L}_2]\text{X}$ .

### 8.1 $[\text{Rh}(\text{NO})\text{L}_3]$ Complexes

The most convenient preparation of the triarylphosphine complexes is from *N*-methyl-*N*-nitrosotoluene-4-sulfonamide and hydrated rhodium trichloride in the presence of the phosphine (equation 46). Other, less convenient, routes to this class of compound exist. The crimson-red crystals of the tris(triphenylphosphine) complex (45) contain three independent molecules, each of which has a bent nitrosyl group. In the gas phase or in solution  $[\text{Rh}(\text{NO})(\text{PF}_3)_3]$  appears to contain a linear  $\text{Rh}-\text{N}-\text{O}$  group, although this may be an artifact of the methods of structure determination. The very reactive triphenylphosphine compound converts other metal complexes to their nitrosyls (equations 47–49) and itself undergoes a variety of addition and ligand-substitution reactions (Scheme 22). The sulfur dioxide complex is noteworthy in that the ligand is bound through both sulfur and oxygen.

Scheme 22

## 8.2 $[\text{RhX}_2(\text{NO})\text{L}_2]$ Complexes

The most convenient preparation of the archtypical complex  $[\text{RhCl}_2(\text{NO})(\text{PPh}_3)_2]$  again involves the reaction between *N*-methyl-*N*-nitrosotoluene-4-sulfonamide and hydrated rhodium trichloride. Many other preparative methods exist; in particular, several other nitrosyl complexes can be converted to  $[\text{RhCl}_2(\text{NO})(\text{PPh}_3)_2]$ . Dichloro(nitrosyl)*bis*(triphenylphosphine)rhodium has the square-pyramidal structure (46). The nitrosyl group is bent and both nitrogen and oxygen atoms lie on the  $\text{RhP}_2$  plane. Surprisingly, the analogs of this complex cannot be obtained from it by metathetical reactions but must instead be prepared from the appropriate starting materials. Indeed, this class of

compound is singularly unreactive, in marked contrast to  $[\text{Rh}(\text{NO})\text{L}_3]$ .

Analogues of the dichloro complex are prepared by a variety of methods, many of which are specific for single compounds. The dibromo complexes can be prepared using nitrosyl bromide or from *N*-methyl-*N*-nitrosotoluene-4-sulfonamide and rhodium tribromide. Replacement of the tribromide by the trichloride and an alkali metal iodide gives diiodo complexes (equations 50 and 51).

Nitric acid converts hydridorhodium(I) complexes to the *bis*(nitrato) complex (equation 52). Other examples

of these complexes can be obtained from silver nitrate and a six-coordinate carbonyldichloronitrosyl complex. It is also possible to prepare a green chloro nitro complex from chlororhodium(I) complexes and oxides of nitrogen or NOCl (equations 53 and 54). However, no dinitro complex has yet been prepared. *Bis*(carboxylato) complexes are prepared very simply by the reaction of carboxylic acids with aerated solutions of  $[\text{Rh}(\text{NO})(\text{PPh}_3)_3]$  (equation 55). Most of these methods are equally applicable to the production of triphenylarsine complexes. The dihalo complexes may also be prepared from  $\text{AsPh}_3$  and halonitrosylrhodium complexes. Although all these complexes are believed to have structure (46), *cis* basal ligands must be present in  $[\text{Rh}(\text{NO})\text{Cl}(\text{NO}_2)(\text{dppe})]$  and  $[\text{Rh}(\text{NO})(\text{SO}_4)(\text{PPh}_3)_2]$ . The latter structure has also been established for  $[\text{Rh}(\text{NO})\text{Br}_2\{\text{P}(\text{OPh})_3\}_2]$ . Some thionitrosyl complexes of this stoichiometry have also been prepared but are of doubtful provenance.

### 8.3 Cationic Complexes

Both mono and dinitrosyl cations may be prepared. Salts of the tetrahedral dinitrosyl cation can be prepared either from rhodium nitrosyls (equation 56) or by addition of nitric oxide to ionic rhodium(I) complexes (equation 57). Both nitrosyl groups in complex (47) are bent. The action of dppe upon the *bis*(triphenylphosphine) complex produces N<sub>2</sub>O. Penta- and hexacoordinate mononitrosyl cations are more common and are usually prepared by the action of NOPF<sub>6</sub> or NOBF<sub>4</sub> on rhodium(I) complexes in organonitrile solvents (equation 58). The principal reactions of the complexes are substitutions of the nitrile ligands (equations 59–61). A noteworthy feature of (48),  $[\text{Rh}(\text{NO})(\text{MeCN})_3(\text{PPh}_3)_2]^+$ , is that the MeCN ligand *trans* to the bent nitrosyl group is said to be bent.

## 1 INTRODUCTION

The organometallic chemistry of rhodium continues to comprise a substantial portion of the field of organotransition metal chemistry. Some highlights of the work published since the appearance of the previous report<sup>1</sup> include substantial progress in the activation of C–H bonds in

homogeneous systems, the synthesis of a large number of complexes containing vinylidene ( $=\text{C}=\text{CRR}'$ ) and allenylidene ( $=\text{C}=\text{C}=\text{CRR}'$ ) ligands and the chemistry of rhodium alkyl complexes containing tridentate nitrogen-donor ligands in place of the more traditional phosphine ligands.

A comprehensive work covering the organometallic chemistry of rhodium for the period 1982–1994<sup>2</sup> has appeared as have reviews of rhodium allenylidene complexes,<sup>3</sup> cationic rhodium arene complexes,<sup>4</sup> and the involvement of rhodium complexes in C–C coupling reactions.<sup>5</sup> Rhodium complexes are mentioned in a review of the use of “short bite” ligands (particularly DPPM) in cluster synthesis<sup>6</sup> and in reviews of the organometallic chemistry of porphyrin compounds,<sup>7</sup> complexes containing both heavy main group elements and transition metals,<sup>8</sup> complexes containing  $\sigma$ - $\pi$  bridging vinyl, alkenyl, and related ligands,<sup>9</sup> complexes of polyynes,<sup>10</sup> homogeneous catalysis in water,<sup>11</sup> “very mixed” metal–carbonyl cluster compounds (e.g.  $\text{Cp}_2\text{Cr}_2\text{Rh}(\text{COD})(\mu_3\text{-S})_2(\mu\text{-SBU}')(\text{CO})_2$ ),<sup>12</sup> and the transition metal assisted oligomerization of phosphalkynes.<sup>13</sup>

The emphasis in the present chapter will be on recent developments in the area of organorhodium chemistry, and as there have been few reports of new synthetic methodologies, the new practitioner is referred to the previous report<sup>1</sup> for references to established procedures.

## 2 COMPOUNDS WITH RHODIUM–CARBON $\sigma$ -BONDS

### 2.1 Alkyl and Aryl Complexes

In contrast to the impression that might be gained from earlier work, the presence of “soft” phosphine or arsine ligands is not required for the preparation of stable alkyl or aryl rhodium complexes. Considerable use has recently been made of the tridentate, nitrogen-donor ligands Cn (**1**, R = H (also called tacn)), Cn\* (**1**, R = Me), and Tp' (**2**, R = R' = Me; R'' = H) in studying reactions of alkylrhodium complexes, particularly those involving reductive eliminations to form C–H bonds, where mounting evidence for the formation of  $\sigma$ -complexes (*see Dihydrogen Complexes & Related Sigma Complexes*) of hydrocarbons with rhodium has been obtained. These ligands are considered to be analogs of the cyclopentadienyl ligands but with different steric and electronic properties.

Alkylation of  $\text{CnRhCl}_3$  by standard methods (equation 1) yields  $\text{CnRhR}_3$  (R = Me,

Et, Ph, vy, Bu<sup>n</sup>, *n*-hexyl, *n*-decyl). Protonation of CnRhR<sub>3</sub> (R = Me, Et, Ph, Bu<sup>n</sup>, *n*-hexyl, *n*-decyl) with two equivalents of HOTf followed by addition of a phosphorus ligand (L = PMe<sub>3</sub>, P(OMe)<sub>3</sub>) and reduction with NaBH<sub>4</sub> (equation 2) yields alkyl hydride (see **Hydride Complexes of the Transition Metals**)

complexes [CnRh(H)R(L)]OTf, which together with some Cn\* analogs, were used to study the reductive elimination of alkane (RH). For R = Me, the half-life for the elimination of methane at 80 °C was 7 h indicating this to be a particularly stable alkyl hydride complex of rhodium. Heating [CnRh(H)R(L)]OTf (R = *n*-Bu, *n*-hexyl, *n*-decyl) in benzene forms [CnRh(H)(C<sub>6</sub>H<sub>5</sub>)(L)]OTf via the activation of a C–H bond (see **Alkane Carbon–Hydrogen Bond Activation**) of benzene by the reductive elimination product, {(Cn)Rh(L)}. The same process using [CnRh(D)R(L)]OTf led to deuterium incorporation into *both* terminal methyl groups of the product alkane leading to the proposal that the eliminated alkane remains associated with the {CnRh(L)} fragment, presumably via an Rh···H–C interaction (see **Dihydrogen Complexes & Related Sigma Complexes**), and that the metal migrates down the alkane chain through a series of such interactions.<sup>14</sup>

Protonation of Cn\*Rh(vy)<sub>3</sub> with HOTf yields the allyl complex [Cn\*Rh(vy)(η<sup>3</sup>-CH<sub>2</sub>CHCHMe)]OTf (see also Section 4.1) in which coupling of two of the vinyl groups is proposed to proceed via an alkylidene intermediate (equation 3).<sup>15</sup>

The starting point for the formation of alkylrhodium complexes containing the Tp' ligand is Tp'Rh(CNR')Cl<sub>2</sub> (R' = CH<sub>2</sub>CMe<sub>3</sub>), which is prepared by replacement of the weakly bound acetonitrile ligand in Tp'Rh(NCMe)Cl<sub>2</sub> by the isocyanide. Conversion of this to the alkyl hydrides Tp'Rh(CNR')(H)(R) (R = CH<sub>2</sub>CD<sub>3</sub>, Pr<sup>n</sup>, Pr<sup>i</sup>, vy, *cyclo*-C<sub>3</sub>H<sub>5</sub>) (see **Hydride Complexes of the Transition Metals**) proceeds via equation (4). When R = *cyclo*-C<sub>3</sub>H<sub>5</sub>, rearrangement to the

metallacyclobutane isomer occurs readily and is proposed to involve reductive elimination to give a σ-cyclopropane complex followed by insertion of the metal into a strained C–C bond. On heating, this rearranges again to the isomeric propene complex from which the olefin is liberated under photolysis with the solvent benzene undergoing C–H oxidative addition (see **Alkane Carbon–Hydrogen Bond Activation**) to the reactive {Tp'Rh(CNR')} fragment (equation 5).

Reduction of Tp'Rh(CNR')(vy)Cl with Cp<sub>2</sub>ZrH<sub>2</sub> forms Tp'Rh(CNR')(vy)(H), which rearranges at room temperature to the ethylene complex Tp'Rh(CNR')(η<sup>2</sup>-C<sub>2</sub>H<sub>4</sub>). To explore the regiochemistry of the C–H oxidative addition process in related systems, the {Tp'Rh(CNR')} fragment was generated by photolysis of (3) in three liquid olefins. For R = H and Me, oxidative addition occurs at a methyl C–H bond (see **Alkane Carbon–Hydrogen Bond Activation**) to form the corresponding allyl hydride (equation 6). When R = Me, C–H reductive elimination occurs over three days at room temperature in benzene solution to form the propene complex

$\text{Tp}'\text{Rh}(\text{CNR}')(\eta^2\text{-CH}_2=\text{CHMe})$ , while for  $\text{R} = \text{Me}$ , the reductive elimination occurs more readily and the olefin complex is less stable so that the ultimate product is the benzene activation product  $\text{Tp}'\text{Rh}(\text{CNR}')(\text{H})(\text{C}_6\text{H}_5)$ . Photolysis of (3) (see *Photochemistry of Transition Metal Complexes*) in liquid *t*-butylethylene leads to oxidative addition of a vinylic C–H (see *Alkane Carbon–Hydrogen Bond Activation*) bond yielding  $\text{Tp}'\text{Rh}(\text{CNR}')(\text{H})(\text{CH}=\text{CHCMe}_3)$ , presumably because the bulk of the *t*-butyl group prevents this end of the molecule getting sufficiently close to the metal. This vinyl hydride complex is considerably more resistant to reductive elimination than the allyl hydride species and again the ultimate decomposition product is  $\text{Tp}'\text{Rh}(\text{CNR}')(\text{H})(\text{C}_6\text{H}_5)$ . The methyl hydride complex  $\text{Tp}'\text{Rh}(\text{CNR}')(\text{H})(\text{CH}_3)$  in  $\text{C}_6\text{D}_6$  solution at room temperature undergoes H/D exchange to initially form  $\text{Tp}'\text{Rh}(\text{CNR}')(\text{H})(\text{CH}_2\text{D})$  and more slowly the solvent activation product  $\text{Tp}'\text{Rh}(\text{CNR}')(\text{D})(\text{C}_6\text{D}_5)$  plus  $\text{CH}_3\text{D}$ . The rate of reductive elimination of methane in  $\text{C}_6\text{H}_6/\text{C}_6\text{F}_6$  mixtures depends on the concentration of benzene. Both observations are consistent with the presence of a rhodium–methane  $\sigma$ -complex (see *Dihydrogen Complexes & Related Sigma Complexes*), which forms subsequent to the reductive elimination.<sup>16</sup>

Photolysis of  $\text{Tp}'\text{Rh}(\text{CO})_2$  in alkane solution (see *Photochemistry of Transition Metal Complexes*) forms  $\text{Tp}'\text{Rh}(\text{CO})(\text{H})(\text{R})$  ( $\text{R} = n\text{-pentyl}, n\text{-hexyl}, n\text{-heptyl}, i\text{-octyl}$ ) via oxidative addition of a C–H bond (see *Alkane Carbon–Hydrogen Bond Activation*) to the reactive intermediate  $\{\text{Tp}'\text{Rh}(\text{CO})\}$ . The wavelength dependence of the quantum yield suggests the involvement of two different excited states of differing reactivity. The lack of a thermal reaction in the dark suggests that a species with an  $\eta^2\text{-Tp}'$  ligand is not involved. The analogous reaction with the modified tris-(pyrazolylborate) ligand (4) resulted in oxidative addition of a C–H bond of the isopropyl substituent to the metal to form the pair of isomers shown in equation (7). These were shown to thermally

interconvert via a rate-determining C–H reductive elimination/oxidative addition process within a single arm of the ligand, and without inversion of configuration at the metal.<sup>17</sup> The reaction of Lewis base ligands ( $\text{L} = \text{py}, \text{MeCN}$ ) with  $\text{Tp}'\text{Rh}(\text{C}_2\text{H}_4)_2$  and subsequent chemistry is outlined in equation (8). These results are interpreted as shown in

equation (9).

The key feature is the presence of a small equilibrium quantity of the vinyl hydride complex  $\text{Tp}'\text{Rh}(\text{H})(\text{CH}=\text{CH}_2)(\eta^2\text{-C}_2\text{H}_4)$  formed by C–H oxidative addition of one of the ethylene ligands. The formation of  $\text{Tp}'\text{Rh}(\text{C}_2\text{H}_5)(\text{C}_6\text{H}_5)(\text{L})$  and its deuterated analog are postulated to arise from coordination of benzene to the ethylene-loss species  $\{\text{Tp}'\text{Rh}(\eta^2\text{-C}_2\text{H}_4)\}$  followed by C–H oxidative addition (see *Alkane Carbon–Hydrogen Bond Activation*).<sup>18</sup>

A series of more highly substituted ( $\text{R} = \text{R}' = \text{Me}, \text{CF}_3$ ;  $\text{R}' = \text{H}, \text{R} = \text{CF}_3$ ;  $\text{R}' = \text{Me}, \text{R}'' = \text{H}, \text{R} = \text{Me}$ ;  $(\text{R}, \text{R}') = -(\text{CH}_2)_3-, -(\text{CH}_2)_4-$ ) and unsymmetrical ( $\text{R} = \text{Ph}, \text{R}' = \text{Me}$ ;  $\text{R}'' = \text{H}$  on two pyrazolate rings and  $\text{R}, \text{R}' = \text{Me}, \text{Ph}; \text{Me}, \text{Me}; \text{Et}, \text{Et}$  on the third), examples of (2) ( $\text{Tp}^{\text{R}, \text{R}'}$ ) were used to prepare  $(\text{Tp}^{\text{R}, \text{R}'}\text{RhL}_2)$  ( $\text{L} = \text{CO}, \text{L}_2 = \text{COD}$ ). Experimental and theoretical studies of the structures and conformational preferences of these complexes were performed.<sup>19</sup>

Several further experimental and theoretical studies of the oxidative addition of methyl iodide to Rh(I) complexes have been reported, in part because of its importance in the rhodium-catalyzed carbonylation of methanol (see *Carbonylation Processes by Homogeneous Catalysis*) to

acetic acid (equation 10).

These include the reaction with  $(\eta^2\text{-Tp}')\text{Rh}(\text{L})(\text{CO})$  ( $\text{L} = \text{PMe}_3, \text{PMe}_2\text{Ph}, \text{PMePh}_2, \text{PPh}_3$ ) where the initial product is  $[(\eta^3\text{-Tp}')\text{Rh}(\text{L})(\text{CO})\text{Me}]\text{I}$ , and slow conversion to the acyl derivative  $(\eta^3\text{-Tp}')\text{Rh}(\text{L})(\text{C}(\text{O})\text{Me})(\text{I})$  ensues. The second order kinetics, a correlation of rates with the basicity of  $\text{L}$  and a large negative value for  $\Delta S^\ddagger$  indicate an associative activation process. The much lower reactivity of analogous bis(pyrazolyl)borate complexes suggests that the ability of  $\text{Tp}'$  to change from  $\eta^2$  to  $\eta^3$  coordination at some point on the reaction coordinate is important to facilitating the process.<sup>20</sup> With  $[\text{Rh}(\mu\text{-Cl})(\text{Pr}^i\text{P})_2]_2$  and  $\text{RhCl}(\text{PEt}_3)_3$  at  $-20^\circ\text{C}$ , methyl iodide (see **Carbon–Carbon & Carbon–Heteroatom Activation**) forms 5- and 6-coordinate oxidative adducts, respectively, but with  $(\text{Pr}^i\text{P})_2\text{Rh}(\eta^2\text{-OTf})$ , no reaction occurs at room temperature even in the presence of excess methyl iodide. Evidently, the nature of the anionic ligand (chloride is the better donor) and possibly the coordination number at  $\text{Rh}(\text{I})$  are important factors for the success of the reaction.

A low (circa 1%) steady state concentration of  $[\text{Rh}(\text{CH}_3)(\text{CO})_2\text{I}_3]^-$  has been detected spectroscopically when salts of  $[\text{RhI}_2(\text{CO})_2]^-$  are dissolved in methyl iodide confirming the identity of the proposed initial oxidative adduct of methyl iodide to  $[\text{RhI}_2(\text{CO})_2]^-$  in the methanol carbonylation process (see **Carbonylation Processes by Homogeneous Catalysis**) (right side of equation 10). The transition state for this initial step has been explored by ab initio calculations (see **Molecular Orbital Theory**) and two reasonable models were obtained. Both involve attack of the metal on the methyl group with the more energetically favored occurring opposite the iodine. This is the “classical” model for the transition state that leads to an inversion at carbon, and is also preferred on the basis of a comparison of the observed and calculated kinetic isotope effects of the reaction. The other plausible transition state involves attack adjacent to iodine and leads to retention at carbon.<sup>21</sup> Another computational study explored the conversion of  $[\text{Rh}(\text{CH}_3)(\text{CO})_2\text{I}_3]^-$  to  $[\text{Rh}(\text{C}(\text{O})\text{CH}_3)(\text{CO})\text{I}_3]^-$  (lower right of equation 10) using DFT methods (see **Molecular Orbital Theory**), from which it was concluded that it is

a migratory insertion process with the methyl group migrating to a carbonyl ligand.<sup>22</sup> In a related study, spectroscopic and structural evidence for this migration of a methyl group between rhodium and a coordinated carbonyl ligand were obtained, as outlined in equation (11). In the first step, the diastereomer shown comprises 89% of the product acyl

complex and the subsequent deinsertion/insertion processes occur stereospecifically indicating movement of the methyl group.<sup>23</sup> Both the oxidative addition and methyl migration steps have been independently studied in detail in the system depicted in equation (12).<sup>24</sup> Also reported is the cis oxidative addition of methyl iodide to both

rhodium centers in  $\text{Pd}\{(\mu\text{-pz})(\mu\text{-SBu}^t)\text{Rh}(\text{CO})(\text{P}(\text{OMe})_3)\}_2$ , which is followed by methyl migration to carbon monoxide on both centers such that the two acyl ligands formed are on the same side of the mean molecular plane.<sup>25</sup>

Laser flash photolysis (see **Luminescence Behavior & Photochemistry of Organotransition Metal Compounds** and **Photochemistry of Transition Metal Complexes**) coupled with rapid infrared analysis of the solution species has proved a powerful tool for the detection of unstable intermediates, and has seen considerable application on experimental studies of the C–H oxidative addition reaction (see **Alkane Carbon–Hydrogen Bond Activation**). Application to toluene solutions of  $\text{Cp}^*\text{Rh}(\text{PMe}_3)(\eta^2\text{-C}_2\text{H}_4)$  has allowed detection of the intermediate  $\text{Cp}^*\text{Rh}(\text{PMe}_3)(\eta^2\text{-toluene})$ , and by following the subsequent conversion to  $\text{Cp}^*\text{Rh}(\text{PMe}_3)(\text{H})(\text{C}_6\text{H}_4\text{Me})$ ,

activation parameters for the C–H oxidative addition process have been derived. In a related study, the reductive elimination of this last species and analogous aryl hydride complexes showed that the activation barrier for the process increased and the transition state became “looser” as the substituents on the aryl group became more electron-withdrawing. It appears now that  $\eta^2$ -coordination of arenes to  $\{\text{Cp}^*\text{Rh}(\text{PMe}_3)\}$  and related coordinatively unsaturated species precedes C–H oxidative addition, and control of the degree to which this occurs seems to depend on the extent to which the  $\eta^2$ -coordination disrupts the resonance stabilization of the arene.<sup>26</sup>

With the development of powerful methods for molecular orbital calculations (e.g. DFT) (see **Molecular Orbital Theory**), several computational studies of the C–H oxidative addition (see **Alkane Carbon–Hydrogen Bond Activation**) process have been undertaken. One has used  $\{\text{CpRh}(\text{PH}_3)\}$  to model the reactive intermediate  $\{\text{Cp}^*\text{Rh}(\text{PMe}_3)\}$  proposed for the reaction shown in equation (13). The results

suggest that reaction occurs from a singlet potential-energy surface via an initial  $\sigma\text{-H-C}_3\text{H}_5$  complex through a single transition state to the cyclopropyl hydride complex, which is the kinetic product. They also indicate that the subsequent thermal rearrangement to the metallacyclobutane complex proceeds via C–H reductive elimination to the same  $\sigma\text{-H-C}_3\text{H}_5$  complex followed by metal insertion into a C–C bond (see **Carbon–Carbon & Carbon–Heteroatom Activation**) (see also equation 5).<sup>27</sup> In contrast, DFT calculations on the oxidative addition of methane to  $\{\text{CpM}(\text{L})\}$  ( $\text{M} = \text{Rh}, \text{Ir}$ ;  $\text{L} = \text{CH}_2, \text{CO}, \text{SH}_2, \text{PH}_3$ ) suggest that C–H oxidative addition should proceed from the triplet state since it is said that the singlet-triplet splitting (see **Electronic Structure of Organometallic Compounds**) correlates with both  $\Delta H^\ddagger$  and  $\Delta H$  for the process, but no comments are made in the previous paper about this difference.<sup>28</sup> A third study used ab initio methods to probe the preference for intermolecular C–H oxidative addition, as modeled by  $\{\text{CpRh}(\text{PH}_3)\} + \text{CH}_4$ , versus an intramolecular process involving a ligand substituent as modeled by  $\{\text{CpRh}(\text{PH}_2\text{R})\}$  ( $\text{R} = \text{Me}, \text{Et}$ ). The conclusion is that the intermolecular process has a lower activation barrier.<sup>29</sup> In an elaborate computational study, DFT methods that included quantization of vibrational energy, addition of zero-point energy and tunneling effects were used to probe the

conversion of  $\text{RhCl}(\eta^2\text{-H}_2\text{CH}_2)(\text{PH}_3)$  to  $\text{RhCl}(\text{H})(\text{CH}_3)(\text{PH}_3)$ . At 200 K, the calculated rate constant was increased by a factor of 194 over that calculated using classical mechanics to describe the atomic motions along the reaction coordinate. So far there appear not to be sufficient experimental data for comparison.<sup>30</sup> A final paper used DFT methods to explore the C–H activation step in the  $\text{Rh}_2(\text{OAc})_4$  catalyzed coupling of a diazo compound with an alkane that finds significant application in organic synthesis (see **Organic Synthesis Using Metal-mediated Coupling Reactions** and **Organic Synthesis using Transition Metal Carbonyl Complexes**). The results indicate that the diazo compound should coordinate to an axial site on the dinuclear complex via carbon with back-donation of electron density into the C–N  $\sigma^*$  orbital, facilitating extrusion of  $\text{N}_2$  and formation of an intermediate carbene complex (see also Section 2.4 and **Carbene Complexes**). The highly electrophilic carbene carbon then attracts the C–H bond of the alkane leading to the development of a three-center transition state (equation 14).<sup>31</sup>

The early ideas that C–H oxidative addition (see **Alkane Carbon–Hydrogen Bond Activation**) requires constraining the C–H bond to be close to the metal have been shown to be incorrect as many examples of unconstrained, intermolecular C–H oxidative addition are now known. Nevertheless, a considerable number of reports continue to appear on activation of C–H and C–C bonds in constrained, intramolecular systems. One series uses the “pincer” ligands (5) and (6). Reaction of (5) ( $\text{R} = \text{Bu}^t$ ;  $\text{R}_1 = \text{Et}$ ;  $\text{R}_2 = \text{R}_3 = \text{H}$ ) with  $[\text{Rh}(\mu\text{-Cl})(\text{L})_2]_2$  ( $\text{L} = \text{C}_2\text{H}_4, \text{COE}$ ) forms (7), which on prolonged heating converts to (8), conditions under which analogs with a methyl, trifluoromethyl, or  $\beta, \beta, \beta$ -trifluoroethyl group in place of the ethyl group were stable. This indicates (8) formed by  $\beta\text{-H}$  elimination, with the bulk of the tridentate ligand enforcing the necessary coordinative unsaturation in (7) and then enhancing the dissociation of the product olefin. Complex (8) can also be obtained directly from  $[\text{Rh}(\mu\text{-Cl})(\text{L})_2]_2$  ( $\text{L} = \text{C}_2\text{H}_4, \text{COE}$ ) and (5) ( $\text{R} = \text{Bu}^t$ ;  $\text{R}_1 = \text{R}_2 = \text{R}_3 = \text{H}$ ) by oxidative addition of the  $\text{C-R}_1$  ( $=\text{H}$ ) bond. The insertion of Rh into the  $\text{sp}^2\text{-sp}^3$  C–C bond (see **Carbon–Carbon & Carbon–Heteroatom Activation**) in forming (7) rather than a C–H or a  $\text{sp}^3\text{-sp}^3$  C–C bond is suggested to be kinetically controlled. To further explore the factors controlling preferences for C–H (see **Alkane Carbon–Hydrogen Bond Activation**) versus C–C (see **Carbon–Carbon & Carbon–Heteroatom Activation**) activation in these types of complexes, the reaction of (6) ( $\text{X} = \text{OMe}$ ) with  $[\text{Rh}(\text{COE})_2\text{S}_n]\text{BF}_4$  ( $\text{S} = \text{THF}, \text{MeOH}, \text{acetone}$ ) was performed leading to isolation of a mixture of (9)

and (10), which on heating or on evaporation of the solvent converted to (11).

Molecular orbital calculations (see *Molecular Orbital Theory*) indicate that the presence of a highly coordinatively unsaturated 14-electron Rh center is important for both C–C and C–H activation, but that for C–C activation to occur, the methoxy group of the ligand has to be coordinated to bring the central C–CH<sub>3</sub> bond close to the metal. Presumably, coordination of the solvent to the starting Rh(I) complex prevents (6) from binding as a bidentate ligand so this condition is not initially met. Removal of solvent permits additional binding of the methoxy substituent, and following reductive elimination, C–C activation occurs. In contrast to some of the computational studies mentioned earlier, a “direct” C–H oxidative addition (without initial formation of a  $\sigma$ -complex) is indicated by the calculations. Reaction of (5) (R = Ph; R<sub>1</sub> = R<sub>2</sub> = Me; R<sub>3</sub> = H) with Rh(H)(PPh<sub>3</sub>)<sub>4</sub> forms the C–H activation product, (12), which oxidatively adds aryl iodides (Ar = Ph, *p*-XC<sub>6</sub>H<sub>4</sub> (X = Me, OMe, CF<sub>3</sub>), 3,5-(CF<sub>3</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) (equation 15). Complexes (13) on heating undergo transfer of

a methylene group to form (14). This is proposed to occur via reductive elimination of the two Rh–C bonds in (13) followed by insertion of the metal into the C–CH<sub>2</sub>Ar bond (see *Carbon–Carbon & Carbon–Heteroatom Activation*). To probe the feasibility of the reverse transfer (14 to 13), an analog of (12) was reacted with ArCH<sub>2</sub>Br (Ar = *p*-CF<sub>3</sub>C<sub>6</sub>H<sub>4</sub>) and then with phenyl lithium followed by triphenylphosphine (equation 16). The phenyl lithium replaces the bromide ligand to

yield an intermediate with three Rh–C bonds, and coordination of the phosphine induces competitive reductive elimination of either the phenyl and benzyl groups to form the product pair on the left or the benzyl group with the Rh–C bond to the ligand. The latter process is followed by activation of a benzyl C–H bond and reductive elimination of benzene to form the product pair on the right.

Reaction of (5) (R = Bu<sup>t</sup>; R<sub>1</sub> = H; R<sub>2</sub> = R<sub>3</sub> = H, OMe) with [Rh( $\eta^2$ -C<sub>2</sub>H<sub>4</sub>)(CO)(THF)<sub>1,2</sub>][OTf] at room temperature forms a species formulated as (15a,b). The crystal structure shows the presence of an agostic hydrogen on the ring carbon adjacent to the metal indicating that oxidative addition of this C–H bond to the metal has not occurred, and so this is presumably a precursor to complexes like (8). That the agostic hydrogen is not in the plane of the attached ring is taken to indicate that this ring exhibits some degree of arenium

character. In deliberate attempts to generate arenium character in the central ring of the pincer ligand, the reaction sequence of equation (17) ( $R = \text{Bu}^t$ ;

$R' = \text{H}, \text{SiMe}_3$ ) was performed. The structure of the cationic complex showed a significant averaging of the C–C distances in the six-membered ring as compared with the quinoid precursor indicating it to be formulated as a methylene arenium cation. The two products of the reaction at the right of this scheme are characterized as metal stabilized xylylenes. Under forcing conditions, (5) ( $R = \text{Bu}^t$ ;  $R_1 = \text{CF}_3$ ;  $R_2 = R_3 = \text{H}$ ) reacts with  $[\text{Rh}(\mu\text{-Cl})(\text{L})_2]_2$  ( $\text{L} = \text{C}_2\text{H}_4, \text{COE}$ ) with cleavage of the C– $\text{CF}_3$  bond to form (16). Protonation of (16) with HOTf yields the difluoromethylene arenium salt (17). Similar processes occur with the systems shown in equations (18) and (19), where both methylene

arenium and methyl arenium cations were generated. The alkyl arenium compounds appear to have considerably less positive charge in the ring than do the methylene arenium analogs. This proposed to be the result of stabilization of the arene form via an agostic interaction of the  $\text{C}_{\text{ipso}}\text{--}\text{C}_{\text{alkyl}}$  bond with the metal. The transformations depicted in equation (19) indicate that direct transfer of an alkyl group to the methylene arenium cation does not occur. Most recently, reaction of (6) ( $\text{X} = \text{NEt}_2$ ) with  $[\text{Rh}(\mu\text{-Cl})(\text{COE})_2]_2$  has been reported to proceed via oxidative addition of the central methyl group to the metal as observed in related systems. Chemistry following chloride abstraction from the initial product in THF solution is outlined in equation (20). The formation of the methylene

arenium cation in this instance is proposed to be the result of the noncoordinating character of the solvent fluorobenzene and the counterion  $[\text{BARf}]^-$  (see *Boron: Organoboranes*) that forces a high degree of unsaturation upon the 14-electron metal leading to methyl transfer to the ring followed by  $\beta\text{-H}$  elimination.<sup>32,33</sup>

While ligands like (5) that force a C–H bond close to rhodium could be expected to facilitate C–H activation (see

**Alkane Carbon–Hydrogen Bond Activation**), such behavior might not be expected of a monophosphine. However, in the reaction of  $[\text{Rh}(\mu\text{-Cl})(\text{COE})_2]_2$  with four equivalents of  $\text{PhCH}_2\text{CH}_2\text{P}^i\text{Bu}'_2$ , this is observed as the product in **(18)** and conversion to **(19)** occurs on chloride abstraction (see also **(174)**, Section 42).<sup>34</sup> A related situation is obtained when  $[\text{Rh}(\mu\text{-Cl})(\text{Bu}'_2\text{PCH}_2\text{P}^i\text{Bu}'_2)]_2$  is treated with neopentyl lithium where the highly unsaturated, 14-electron metal in the product, **(20)**, is stabilized by an agostic interaction.<sup>35</sup>

Recent work has also focused on the bis(oxazoline) ligands **(21)** ( $\text{R}_1 = \text{R}_2 = \text{Me}$ ,  $\text{R}_2 = \text{H}$ ;  $\text{R}_1 = \text{Me}$ , Et,  $\text{Pr}^i$ ,  $\text{Bu}^i$ ,  $\text{Bu}^t$ , Ph.  $\text{R}' = \text{H}$ , Me). Reaction with  $\text{RhCl}_3 \cdot 3\text{H}_2\text{O}$  forms **(22)** in which there is an agostic interaction with the endo methyl group when  $\text{R}_1 = \text{R}_2 = \text{R}' = \text{Me}$ . On successive reactions with dimethyl zinc (see **Zinc: Organometallic Chemistry**),  $\text{AgOTf}$ , and  $\text{NaBARf}_4$ , **(22)** ( $\text{R}' = \text{Me}$ ,  $\text{R}_2 = \text{H}$ ,  $\text{R}_1 = \text{Pr}^i$ ) forms **(23)** where methyl migration to the aromatic ring (via C–C reductive elimination) occurs on reaction with neutral ligands to form **(24)** ( $\text{L} = \text{CO}$ ,  $\text{C}_2\text{H}_4$ ).<sup>36</sup>

The migratory insertion reactions of ethylene into Rh–H and Rh–C bonds (see **Organic Synthesis using Transition Metal Carbonyl Complexes**; **Organic Synthesis using Transition Metal Complexes Containing  $\pi$ -Bonded Ligands**, and **Organic Synthesis Using Metal-mediated Coupling Reactions**) have been explored by DFT calculations (see **Molecular Orbital Theory**) on  $[\text{CpRh}(\text{PH}_3)(\text{C}_2\text{H}_4)\text{R}]^+$  ( $\text{R} =$

H, Me). Inclusion of relativistic effects was found to be important for results on the model to agree with experiment. For  $\text{R} = \text{H}$ , the calculated transition state was calculated to be close to the reactants, while for  $\text{R} = \text{Me}$ , the transition state is product-like. Both the ethyl and propyl products show an agostic interaction with a  $\beta$ -hydrogen.<sup>37</sup> A second study used DFT methods to explore the oxidative addition of the C–F bond in fluoromethane to unsaturated Rh(I) species modeled by  $\{\text{Rh}(\text{X})(\text{PH}_3)_2\}$  ( $\text{R} = \text{H}$ , Me, Cl). The activation barrier was found to correlate with the magnitude of the singlet-triplet splitting and to be lowered by the presence of  $\pi$ -donor ligands.<sup>38</sup>

## 2.2 Dinuclear Complexes

Considerable interest continues to be shown in the chemistry of dinuclear complexes (see **Dinuclear Organometallic Cluster Complexes**), particularly heterometallic species, containing metal–carbon  $\sigma$ -bonds to determine the extent to which the two metals may be involved in the cleavage and formation of C–H and C–C bonds (see **Carbon–Carbon & Carbon–Heteroatom Activation** and **Alkane Carbon–Hydrogen Bond Activation**). With the symmetrical complex  $[\text{Rh}(\mu\text{-pz})(\text{CNBu}'_2)_2]_2$ , methyl iodide adds (see **Carbon–Carbon & Carbon–Heteroatom Activation**) to both metal centers forming  $[\text{Rh}_2(\mu\text{-pz})_2(\mu\text{-I})(\text{Me})_2(\text{CNBu}'_4)]\text{I}$  but with  $(\text{COD})\text{Rh}(\mu\text{-pz})_2\text{Rh}(\text{CNBu}'_2)_2$ , only the metal coordinated to the isocyanide reacts. Evidently that metal is more basic. Similar results are seen with  $\text{RCH}_2\text{Cl}$  ( $\text{R} = \text{vy}$ ,  $\text{C}(\text{=O})\text{Me}$ ,  $\text{C}(\text{=O})\text{OMe}$ , Ph) where both metals are alkylated in the former complex but only one is alkylated in the latter complex. Both these results suggest that the metal atoms are acting independently in the oxidative addition. By contrast, addition of one equivalent of  $\text{I}_2$  to  $[\text{Rh}(\mu\text{-pz})(\text{CNBu}'_2)_2]_2$  forms the *symmetrical* adduct  $[\text{Rh}(\mu\text{-pz})\text{I}(\text{CNBu}'_2)]_2$ . The difference is attributed to the polarity of the C–I bond in methyl iodide, which makes it susceptible to attack by a nucleophilic metal while the nonpolar iodine functions more as a simple oxidizing agent. This is also suggested by the observation that  $[\text{Rh}(\mu\text{-pz})(\text{CNBu}'_2)_2]_2$  can be oxidized to  $\{[\text{Rh}(\mu\text{-pz})(\text{MeCN})(\text{CNBu}'_2)_2]\}^{2+}$  by two equivalents of ferricinium hexafluorophosphate, and on reaction of the cation with iodide ion,  $[\text{Rh}(\mu\text{-pz})\text{I}(\text{CNBu}'_2)]_2$  is again formed. In the case of  $\text{RCHCl}_2$  ( $\text{R} = \text{H}$ ,  $\text{C}(\text{=O})\text{Me}$ ,

C(=O)OMe, Ph),  $[\text{Rh}(\mu\text{-pz})(\text{CNBu}^t)_2]_2$  forms  $\text{Rh}_2(\mu\text{-pz})_2(\mu\text{-CHR})\text{Cl}_2(\text{CNBu}^t)_4$  and here the unsymmetrical dimer also gives an analogous product.<sup>39</sup>

Most numerous are reports on heterobimetallic complexes bridged by two DPPM ligands. The first example is (25) ( $X = \text{BF}_4^-$ ,  $\text{OTf}^-$ ). As depicted below, only the ligands in the equatorial plane of this and related complexes will be shown in the ensuing discussion for simplicity. Neutral ligands,  $L (= \text{C}_2\text{H}_4, \text{various allenes})$  add to iridium in (25) to cause one carbonyl ligand to become semi-bridging while dimethylacetylene dicarboxylate ( $R = \text{CO}_2\text{Me}$ ) oxidatively adds across both metals (equation 21). Allyl halides undergo simple

oxidative addition (see **Carbon–Carbon & Carbon–Heteroatom Activation**) to (25) at a low temperature but on warming, C–C coupling with the acetylide occurs (equation 22 ( $R = \text{CH}_2\text{CHCH}_2$ ;  $Y = \text{Cl}, \text{Br}$ )). Protonation of (25)

probably occurs initially at iridium, but the characterized product contains a bridging hydride ligand, which is induced to couple with the acetylide ligand and form a vinylidene-bridged species (equation 23). In contrast to internal alkynes,

terminal

alkynes undergo C–H oxidative addition (see **Alkane Carbon–Hydrogen Bond Activation**) to the iridium center in (25) to form a bis-acetylide complex.<sup>40</sup>

The neutral complex  $\text{Rh}(\text{CO})(\mu\text{-DPPM})_2\text{Ir}(\text{CO})_2$  is unreactive toward even excess methyl iodide but is alkylated by  $\text{MeOCH}_2\text{I}$  and then methyl triflate (equation 24 ( $R = \text{MeOCH}_2$ )). It can, however, be methylated at iridium by methyl triflate and the

subsequent reactions of this cationic methyl derivative with dihydrogen and with isocyanides are outlined in equations (25) and (26). The coupling of the methyl group with

the isocyanide is of note particularly since, in the reaction of the methyl complex with acetylene, the alkyne oxidatively adds to both metals to initially form the dimetallated olefin complex but then couples with one of the DPPM ligands and not with the methyl group (equation 27).<sup>41</sup> By contrast, in the same reaction with dimethylacetylene

dicarboxylate, following the formation of an intermediate dimetallated olefin complex, coupling with the methyl group does occur. With phenyl acetylene, oxidative addition of the alkyne C–H bond to iridium occurs at a low temperature to form an acetylide hydride species, which on warming eliminates methane and ultimately reacts with a second alkyne by C–H oxidative addition to give  $[\text{Rh}(\text{CO})(\mu\text{-H})(\mu\text{-DPPM})_2(\mu\text{-}\eta^1:\eta^2\text{-C}\equiv\text{CPh})\text{Ir}(\text{C}_2\text{Ph})(\text{CO})]^+$ .<sup>42</sup>

At a low temperature,  $\text{Rh}(\text{CO})(\mu\text{-DPPM})_2\text{Mn}(\text{CO})_3$  oxidatively adds 3-butyne-2-one to form a dimetallated olefin complex, which rearranges on warming to the vinylidene-bridged isomer (equation 28 ( $\text{R} = \text{C}(=\text{O})\text{Me}$ )). This last complex reacts

with triflic acid and methyl triflate as shown in equation (29). With the alkynes  $\text{RC}\equiv\text{CR}$ ,

$\text{Rh}(\text{CO})(\mu\text{-DPPM})_2\text{Mn}(\text{CO})_3$  also forms dimetallated olefin complexes, which can be converted to vinyl derivatives by protonation (equation 30 ( $\text{R} = \text{CF}_3, \text{CO}_2\text{Me}$ )).

Protonation of  $[\text{Rh}(\text{CO})(\mu\text{-DPPM})_2\text{Os}(\text{CO})_3]^+$  by  $\text{HBF}_4 \cdot \text{Et}_2\text{O}$  in acetonitrile forms  $[\text{Rh}(\text{MeCN})(\mu\text{-CO})(\mu\text{-H})(\mu\text{-DPPM})_2\text{Os}(\text{CO})_2]^+$ , some of whose chemistry is outlined in equations (31) and (32). The reaction of  $[\text{Rh}(\text{CO})(\mu\text{-DPPM})_2\text{Os}(\text{CO})_3]^+$  with *n*-butyl lithium

results in abstraction of a proton from the methylene carbon of one DPPM ligand rather than alkylation of one of the metal atoms, and the same product is obtained if the first step of equation (32) is performed under a CO atmosphere. Protonation of  $\text{Rh}(\text{Me})(\mu\text{-DPPM})_2\text{Os}(\text{CO})_3$  (see equation 31) at  $-80^\circ\text{C}$  occurs at osmium to form (26). On warming, the methyl group migrates to osmium via an intermediate in which the hydride ligand bridges both metals, methane is eliminated, and the resulting coordinatively unsaturated osmium atom undergoes oxidative addition of an *o*-C–H bond of one DPPM phenyl group to yield (27).

The neutral hydride complex  $\text{Rh}(\text{CO})(\mu\text{-DPPM})_2\text{Os}(\text{H})(\text{CO})_2$  reacts with propyne and allenes to form vinyl derivatives (equation 33 ( $\text{R} = \text{H}, \text{Me}$ )). That the vinyl groups are

attached to rhodium despite the expectation of a stronger Os–C bond is attributed to the formal configuration  $\text{Rh}^{\text{I}}/\text{Os}^0$  being favored. In the case of allene itself, a minor amount of  $(\eta^3\text{-C}_3\text{H}_5)\text{Rh}(\mu\text{-DPPM})_2(\text{CO})_3$  is also seen. All of the vinyl complexes react with one equivalent of  $\text{H}^+$  or  $\text{Me}^+$  at the osmium center, while a second equivalent of  $\text{H}^+$  adds to the  $\beta$ -carbon of the vinyl group to convert this substituent to an alkylidene (equation 34) (see also Section 2.4).

Vinyl complexes can also be obtained from the reaction of  $\text{Rh}(\text{CO})(\mu\text{-H})(\mu\text{-DPPM})_2\text{M}(\text{CO})_3$  with alkynes (equation 35) ( $\text{X} = \text{H}$ ;  $\text{M} = \text{Mo}$ ;  $\text{R}' = \text{R} = \text{CF}_3$ ,  $\text{CO}_2\text{Me}$ .  $\text{R}' = \text{H}$ ;  $\text{R}'' = \text{C}(\text{=O})\text{Me}$ ,  $\text{CO}_2\text{Me}$ ), while action of Grignard reagents on the chloride-bridged analogs forms related compounds (equation 35) ( $\text{X} = \text{Cl}$ ;  $\text{M} = \text{Mo}$ ;  $\text{R} = \text{vy}$ ,  $\text{Me}$ ,  $\text{Ph}$ ,

$\text{CH}_2\text{CH}=\text{CH}_2$ .  $\text{M} = \text{W}$ ;  $\text{R} = \text{vy}$ ). With benzylmagnesium chloride under  $\text{CO}$ , this latter reaction forms the acyl

complexes  $\text{Rh}(\text{C}(\text{=O})\text{CH}_2\text{Ph})(\mu\text{-DPPM})_2\text{M}(\text{CO})_4$   $\text{M} = \text{Mo}$ ,  $\text{W}$ ). The vinyl complex from equation (35) is protonated at a low temperature to give an ethylidene derivative, which on warming rearranges to an ethylene complex (equation 36).

Because conversion of the ethylidene ligand to the ethylene ligand is facile, attempts to couple the ethylidene ligand with alkynes failed and only substitution of the olefin by the alkyne occurred.<sup>42</sup>

In the  $\text{Rh}/\text{Mo}$  and  $\text{Rh}/\text{W}$  complexes, it was hoped to study the effect that the two different metals might have on C–C and C–H coupling reactions (*see Organic Synthesis Using Metal-mediated Coupling Reactions*), but in most instances, it proved impossible to put a hydride or a second organic ligand on one of the metal atoms. This goal was realized to some extent in the  $\text{Rh}/\text{Ru}$  system depicted in equation (37) ( $\text{R} = \text{R}' = \text{CO}_2\text{Me}$ ,  $\text{CO}_2\text{Et}$ ,  $\text{CF}_3$ .  $\text{R} = \text{Me}$ ;  $\text{R}' = \text{CH}(\text{OEt})_2$ ,  $\text{CH}_2\text{OH}$ ). It is

proposed that initial addition of the alkyne occurs at the coordinatively unsaturated rhodium center. Attempts to effect the coupling in the “reverse” direction by adding the methylene unit to an alkyne complex were unsuccessful, as C–C coupling did not occur (equation 38). Decarbonylation of the coupling product obtained from equation (37) forms

the alkylidene-bridged species (28), and only in the case where  $\text{R} = \text{CH}_2\text{OH}$  did more extensive coupling occur to give (29).<sup>43</sup>

The dirhodium complex  $\text{Rh}_2(\text{CO})_3(\mu\text{-DPPM})_2$  reacts with methyl triflate to form the acetyl-bridged complex (30), which on heating loses a carbonyl ligand and undergoes methyl migration to the metal yielding  $\text{Rh}_2(\text{CO})(\text{Me})(\mu\text{-CO})(\mu\text{-DPPM})_2$ . This complex is fluxional via a methyl-bridged intermediate.<sup>44</sup> The carbonate-bridged complex (31) is formed when  $(\eta^3\text{-C}_3\text{H}_5)\text{Rh}(\text{Pr}^i)_2\text{PCH}_2\text{PPr}^i_2$  reacts with an excess of methyl formate.<sup>45</sup>

Diarylsilanes react with  $[\text{Rh}(\mu\text{-H})(\text{dippe})]_2$  to form  $[\text{Rh}(\mu\text{-SiAr}_2)(\text{dippe})]_2$ , but with dimethylsilane the product is (32), which is a catalyst precursor for the dimerization of diphenylsilane (see *Silicon: Inorganic Chemistry*).<sup>46</sup> The initial reaction of  $[\text{Cp}^*_2\text{Rh}_2(\mu\text{-CH}_2)_2(\mu\text{-SH})]\text{BPh}_4$  with dimethylacetylene dicarboxylate is the insertion of one alkyne into the S–H bond but the second equivalent of alkyne couples with both methylene groups to form (33).<sup>47</sup>

### 2.3 Vinylidene and Allenylidene Complexes

A considerable amount of work has been done in this area, which has been spurred in part by interest in the synthesis of multimetallic complexes in which the metal atoms are connected by unsaturated chains of several carbon atoms that may serve as “molecular” wires. The initial and still most widely employed synthetic route to vinylidene complexes involves addition of four equivalents of a trialkylphosphine ( $\text{L} = \text{PPr}_3$  hereafter unless otherwise

specified) to  $[\text{Rh}(\mu\text{-Cl})(\text{COE})_2]_2$ , forming the coordinatively unsaturated fragment  $\{\text{Rh}(\text{PPr}_3)_2\}$  (probably weakly solvated), which is reacted in situ with a terminal alkyne (equation 39 ( $\text{Y} = \text{H}$ ;  $\text{R} = \text{CR}'\text{R}''\text{X}$  ( $\text{R}', \text{R}'' = \text{H}$ , alkyl, aryl;  $\text{X} = \text{OH}$ ,  $\text{OMe}$ ,  $\text{NH}_2$ ,  $\text{Cl}$ ))). Depending on the conditions and the nature of  $\text{R}$ ,

some or all of the species shown can be isolated when  $\text{Y} = \text{H}$ , although often the whole transformation can be carried out in one pot. The C–H oxidative addition step can be initiated thermally or photochemically as can the conversion of the acetylide hydride to the vinylidene. More recently, an alternate route using silyl and stannyl alkynes (see *Silicon: Inorganic Chemistry* and *Tin: Organometallic Chemistry*) has been developed that provides for a greater range of substituents on the vinylidene group. A third route uses  $\{\text{Rh}(\text{PPr}_3)_2\}$  together with  $\text{RR}'\text{C}=\text{CHCl}$  ( $\text{R} = \text{Me}$ ;  $\text{R}' = \text{Me}$ ,  $\text{Ph}$ ,  $\text{RR}' = -(\text{CH}_2)_5-$ ) in the presence of sodium. This does not work with  $\text{Me}_2\text{C}=\text{C}=\text{C}=\text{CHCl}$  as this allene simply coordinates unchanged to the rhodium via the central  $\text{C}=\text{C}$ . Expanding on the original route (equation 39),  $\{\text{Rh}(\text{PPr}_3)_2\}$  reacts with butadiyne to form (34) that is converted to (35) on heating.

The reactivity of vinylidene complexes depends to a significant extent on the substituents of the  $\beta$ -carbon. For example, dehydration of (36) ( $\text{R} = \text{R}' = \text{Me}$ ;  $\text{X} = \text{OH}$ ,  $\text{NH}_2$ ,  $\text{Cl}$ ) with deactivated alumina forms the vinyl vinylidene complexes (37), but for  $\text{R} = \text{H}$ ,  $\text{Ph}$ ;  $\text{R}' = \text{Ph}$ ;  $\text{X} = \text{OH}$ , the allenylidene complex (38) is the product. Diazomethane reacts with (38) ( $\text{R} = \text{Ph}$ ;  $\text{R}' = \text{Ph}$ ,  $\text{CF}_3$ ,  $\text{Bu}'$ ) to couple a methylene fragment to the allenylidene ligand and form (39), which isomerizes to (40) on heating. Complex (40), with iodide in place of chloride, can be obtained directly from (38) on reaction with methyl iodide as the carbon source in the presence of  $\text{KI}$  and  $\text{Na}_2\text{CO}_3$ . In further investigations of C–C coupling processes (see *Organic Synthesis Using Metal-mediated Coupling Reactions*), reaction of  $(\eta^3\text{-C}_3\text{H}_5)\text{Rh}(\text{PPr}_3)_2$  with two equivalents of  $\text{HC}\equiv\text{CCH}(\text{Ph})\text{OH}$  yielded the vinylidene acetylide complex (41) ( $\text{R} = \text{CH}(\text{Ph})\text{OH}$ ), but with  $\text{HC}\equiv\text{CCPh}_2\text{OH}$ , only the bis(acetylide),  $\text{Rh}(\text{H})(\text{C}\equiv\text{CCPh}_2\text{OH})_2\text{L}_2$  forms. This

reacts with a third equivalent of the alkyne to form (42) via (43) ( $R = CPh_2OH$ ) as a proposed intermediate. Photolysis (see *Photochemistry of Transition Metal Complexes*) of  $Rh(H)(C\equiv CCPh_2OH)_2L_2$  promotes vinylidene formation (41), ( $R = CPh_2OH$ ) where coupling (see *Organic Synthesis Using Metal-mediated Coupling Reactions*) of the acetylide and vinylidene ligands is promoted by addition of neutral ligands to form (44) ( $R = CPh_2OH$ ), while treatment of the hydride complex with deactivated alumina in the presence of chloride ion yields (45), possibly via the intermediacy of an acetylide allenylidene complex generated by the dehydration of an initially formed vinylidene species.

A stereoselective coupling (see *Organic Synthesis Using Metal-mediated Coupling Reactions*) of alkyl, aryl, or vinyl groups to a vinylidene ligand and subsequent conversion to an allyl ligand has been achieved by the reaction of  $Rh(=C=CHR)ClL_2$  ( $R = H, Bu^t, Ph$ ) with vinylmagnesium bromide to first form (46). This is converted to (47) by reaction

with CO or to (48) (see Section 4.1) on mild heating in benzene solution.

More elaborate coupling reactions (see *Organic Synthesis Using Metal-mediated Coupling Reactions*) include the reaction of  $Rh(=C=C=CRR')(N_3)L_2$  ( $R = R' = Ph$ ,  $p\text{-MeOC}_6\text{H}_4$ ,  $R = Ph$ ,  $R' = Bu^t$ ) with carbon monoxide which promotes migration of the azide group to the  $\gamma$ -carbon forming (49). This loses dinitrogen to give (50) and reacts with  $[Me_3O]BF_4$  to yield

$[Rh(=C=C=CRR')L_2]_2(\mu\text{-N}_3)BF_4$ . The fluoro analog of (38) ( $R = Ph$ ;  $R' = Bu^t$ ,  $Ph$ ) reacts with  $Ph_3Sn-C\equiv C-C\equiv C-SnPh_3$  to form  $[(R(Ph)C=C=C)RhL_2]_2(\mu\text{-C}\equiv C-C\equiv C\text{-})$  and with  $Ph_3Sn-C\equiv CPh$  (see *Tin: Organometallic Chemistry*) to yield (51). Coupling of the acetylide and allenylidene fragments in (51) is initiated by addition of CO at a low temperature forming (52) and on warming CO, incorporation ensues to give (53). In a similar fashion, (54) converts to (55).

The migratory insertion of the allenylidene unit into Rh–O bonds occurs when  $\text{Rh}(\text{C}=\text{C}=\text{C}(\text{Ph})\text{R})(\text{OR}'')\text{L}_2$ , prepared from (38) ( $\text{R} = \text{Ph}$ ,  $p$ -tolyl;  $\text{R}' = \text{Ph}$ ) and  $\text{K}[\text{OBu}^t]$  in benzene/ $t$ -butanol followed by reaction with  $\text{R}''\text{OH}$  ( $\text{R}'' = \text{Ph}$ ,  $\text{MeC}(\text{O})$ ), is reacted with CO forming  $\text{Rh}\{-\text{C}\equiv\text{C}-\text{C}(\text{Ph})(\text{OR}'')\text{R}\}(\text{CO})\text{L}_2$ .

In transformations analogous to those in equation (39),  $\{\text{Rh}(\text{PPr}_3)_2\}$  fragments have been attached to the alkynyl substituents of 1,3,5-triethynylbenzene and various diethynylbenzenes and naphthalenes, and converted to vinylidenes as illustrated in (56) and (57).<sup>48–50</sup>

The process by which vinylidene complexes are formed from  $\eta^2$ -alkyne complexes has been explored by MP2 calculations (see *Molecular Orbital Theory*) on  $\text{RhCl}(\text{PH}_3)_2(\eta^2-\text{C}_2\text{H}_2)$  to model the steps depicted in the top row of equation (39). The C–H oxidative addition step appears facile but there is a high barrier for the migration of the hydrogen as  $\text{H}^+$  to the  $\beta$ -carbon of the alkynyl ligand. Related MO/MM calculations on  $\text{Rh}(\text{H})\text{Cl}(\text{C}_2\text{H})(\text{PPr}_3)_2$  indicate that for the second step, an intermolecular hydrogen transfer has a much lower barrier than does the intramolecular process. Similar calculations were done for  $(\text{PP}_3)\text{M}^+$  ( $\text{M} = \text{Co}$ ,  $\text{Rh}$ ) interacting with acetylene, which also gave a low barrier for C–H oxidative addition where  $\text{M} = \text{Rh}$ . Since no vinylidene complexes were formed in this rhodium system, no calculations were performed for the acetylide to vinylidene transformation although in the cobalt analog it again appears that the hydrogen moves as a proton.<sup>51,52</sup> DFT calculations (see *Molecular Orbital Theory*) have been used in conjunction with FT–Raman spectroscopy on the complexes  $\text{trans}[\text{RhX}(\text{L})(\text{PPr}_3)_2]$  ( $\text{X} = \text{F}$ ,  $\text{Cl}$ ,  $\text{Br}$ ,  $\text{I}$ ,  $\text{Me}$ ,  $\text{C}\equiv\text{CPh}$ ;  $\text{L} = \text{CO}$ ,  $=\text{C}=\text{CH}_2$ ,  $=\text{C}=\text{CHPh}$ ), to obtain a trans influence series for the ligands X, which increase in the order shown.<sup>53</sup>

Protonation of (58) ( $\text{L} = \text{Pcy}_3$ ;  $\text{R} = \text{Ph}$ ,  $\text{CO}_2\text{Me}$ ,  $\text{SiMe}_3$ ) with  $\text{HBF}_4 \cdot \text{Et}_2\text{O}$  forms the vinylidene-bridged complex (59), while analogous protonation of the unsymmetrical isomer of (58) ( $\text{R} = \text{C}(\text{OH})\text{Ph}_2$ ) yields the allenylidene-bridged species (60).<sup>54</sup> A final route to a vinylidene-bridged dinuclear complex is the reaction of  $[\text{Rh}(\mu\text{-pz})(\text{CNBu}^t)_2]_2$  with  $\text{CH}_3\text{CCl}_3$  and triethylamine in benzene to yield  $\text{Rh}_2(\mu\text{-C}=\text{CH}_2)(\mu\text{-pz})_2(\text{CNBu}^t)_4\text{Cl}_2$ .<sup>55</sup>

## 2.4 Carbene Complexes

The complex  $\text{trans}[\text{RhCl}(\eta^2-\text{CH}_2=\text{CH}_2)(\text{SbPr}_3)_2]$  has proven a suitable synthon for a variety of mono- and bimetallic

carbene complexes (see **Carbene Complexes**) (equation 40) ( $L =$

$\text{SbPr}_3^i$ :  $R = R' = \text{Ph}$ ,  $p\text{-tol}$ ,  $p\text{-anis}$ .  $R = \text{Ph}$ ;  $R' = \text{CF}_3$ ). In the mononuclear complexes, the stibine ligands (see **Antimony: Organometallic Chemistry**) can be replaced by trialkylphosphines and -arsines, and when  $R = R' = \text{Ph}$ , the carbene moiety couples (see **Organic Synthesis Using Metal-mediated Coupling Reactions**) with carbon monoxide,  $t$ -butylisocyanide, or ethylene to form, respectively,  $\text{Ph}_2\text{C}=\text{C}=\text{O}$ ,  $\text{Ph}_2\text{C}=\text{C}=\text{N}^+\text{Bu}^t$ , or  $\text{Ph}_2\text{CHCH}=\text{CH}_2$ . Heating  $\text{Rh}(\text{CRR}')\text{CIL}_2$  ( $L = \text{SbPr}_3^i$ ;  $R = R' = \text{Ph}$ ,  $p\text{-tol}$ .  $R = \text{Ph}$ ;  $R' = p\text{-tol}$ ) forms dinuclear (61) containing a bridging tertiary stibine ligand. When  $R = R' = \text{Ph}$ , (61) reacts with CO to form an apparently polymeric material formulated as  $[\text{Rh}(\text{CPh}_2)\text{Cl}(\text{CO})]_n$  but with  $t$ -butylisocyanide the product is (62). With one equivalent of  $\text{Ti}(\text{acac})$ , (61) converts to (63), in which the bridging stibine ligand can be replaced by trimethylphosphine giving (64). This is converted to (65) on reaction with chlorotrimethylsilane.

Treatment of  $\text{Rh}(\text{CRR}')\text{CIL}_2$  ( $L = \text{SbPr}_3^i$ ,  $\text{PPr}_3^i$ ,  $\text{Ph}_n$  ( $n = 0-3$ );  $R = \text{Ph}$ ;  $R' = \text{Ph}$ ,  $p\text{-tol}$ ) with sodium cyclopentadienide forms  $\text{CpRh}(\text{CRR}')\text{L}$  in good yield. When  $L = \text{SbPr}_3^i$ , this ligand can be replaced with CO or  $\text{CNBu}^t$ , but when  $L = \text{PPr}_3^i$ , coupling of these molecules with the carbene ligand again occurs. In an attempt to generate a ketamine by a similar C-N coupling,  $\text{CpRh}(\text{CPh}_2)\text{L}$  ( $L = \text{SbPr}_3^i$ ,  $\text{PPr}_3^i$ ) was reacted with an aryl azide but the product obtained was the tetraazadiene complex (66) ( $R = \text{Ph}$ ,  $p\text{-tol}$ ). The same complex ( $L = \text{CO}$ ) reacts sequentially with  $\text{CuCl}$  and  $\text{NaCp}$  to form (67) while with  $L = \text{PPr}_3^i$ , protonation causes migration of the carbene moiety to the cyclopentadienyl ring to give (68) ( $R = \text{Ph}$ ,  $p\text{-tol}$ ;  $X = \text{Cl}$ ,  $\text{Br}$ ,  $\text{I}$ ,  $\text{O}_2\text{CCF}_3$ ). When the anion of the acid is noncoordinating (e.g. using  $\text{HBF}_4 \cdot \text{Et}_2\text{O}$ ) or methylation is attempted with  $[\text{Me}_3\text{O}]\text{BF}_4$ , attack occurs on the carbene moiety in  $\text{CpRh}(\text{CPh}_2)(\text{L})$  ( $L = \text{PPr}_3^i$ ) and the allyl complex (69) ( $Y = \text{H}$ ,  $\text{Me}$ ) is formed.<sup>56,57</sup> The indenyl complex (70) ( $L = \text{SbPr}_3^i$ ,  $\text{PPr}_3^i$ ) is prepared from  $\text{Rh}(\text{CPh}_2)\text{CIL}_2$  and indenylpotassium, and like its cyclopentadienyl analog, reacts with CO to transfer the carbene moiety to the indenyl ligand (71).<sup>58</sup>

Photolysis (see **Photochemistry of Transition Metal Complexes**) of a solution of  $\text{CpRh}(\text{PMe}_3)(\eta^2\text{-CH}_2=\text{CH}_2)$  in pentafluoroanisole initially forms  $\text{CpRh}(\text{PMe}_3)(\eta^2\text{-C}_6\text{F}_5\text{OMe})$  (two isomers) and then (72). Hydride abstraction from (72) by trityl tetrafluoroborate generates the carbene complex (73).<sup>59</sup> Decarbonylation of  $(\text{H}_2\text{B}(3,5\text{-Me}_2\text{pz})_2)\text{Rh}(\text{CO})_2$  with trimethylamine oxide in pyridine forms  $(\text{H}_2\text{B}(3,5\text{-Me}_2\text{pz})_2)\text{Rh}(\text{CO})(\text{py})$ , which in benzene solution adds methyl iodide to form (74). Heating (74) at  $45^\circ\text{C}$  yields (75) by a rare example of a reverse  $\alpha$ -hydrogen migration. It is proposed

that the formation of (74) involves initial oxidative addition of methyl iodide (*see Carbon–Carbon & Carbon–Heteroatom Activation*) to rhodium followed by migratory insertion of the methyl group which is facilitated by the coordination of the oxygen of the carbonyl group to the Lewis acid boron.<sup>60</sup>

The neutral chloro analog of the “pincer” complex (11) (Section 2.1) can be reduced to a dinitrogen complex and on addition of phenyldiazomethane, a carbene complex results (equation 41 ( $R = \text{Bu}'$ ,  $R' = \text{Me}$ )). An analogous product (77) is obtained at room

temperature for the complex where  $R' = \text{H}$ , but if the diazo compound is added at  $-70^\circ\text{C}$ , (76) is formed first and on warming converts to (77) plus the dinitrogen complex and *trans*-1,2-diphenylethylene. A series of DFT calculations (*see Molecular Orbital Theory*) on the course of the reaction of the diazoalkane to form the carbene complex have been carried out from which it appears that with bulky substituents on phosphorus, conversion of (76) into an  $\eta^1\text{-C}$ -bound diazo complex is critical.<sup>61</sup> The phosphinocarbene (78) ( $R = \text{NPr}_2$ ) forms the carbene complex  $\text{Rh}(=\text{C}(\text{PR}_2)(2,6\text{-(CF}_3)_2\text{C}_6\text{H}_3))\text{Cl}(\text{CO})_2$  when reacted with  $[\text{Rh}(\mu\text{-Cl})(\text{CO})_2]_2$  at  $-50^\circ\text{C}$ , but on warming rearranges to the phosphorus-bound isomer  $\text{Rh}(\text{P}(\text{R})=\text{C}(\text{R})(2,6\text{-(CF}_3)_2\text{C}_6\text{H}_3))\text{Cl}(\text{CO})_2$ . With  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$ , the analogous carbene complex  $\text{Rh}(=\text{C}(\text{PR}_2)(2,6\text{-(CF}_3)_2\text{C}_6\text{H}_3))\text{Cl}(\text{COD})$  is formed which appears to be more stable.<sup>62</sup>

As the reaction of low-valent rhodium complexes with diazoalkanes is frequently used to prepare mono- and dinuclear carbene complexes (*see Carbene Complexes*) (e.g. equation 41), it has been of interest to explore factors controlling the loss of dinitrogen from the initially formed metal complex of the diazoalkane (*vide supra*). To this end, complexes containing the  $\{\text{Rh}(\text{C}(\text{N}_2)\text{R})\}$  unit have been deliberately synthesized by reaction of  $\text{RhClL}_n$  ( $L = \text{PMe}_3$ ,  $n = 4$ ;  $L = \text{PEt}_3$ ,  $n = 3$ ) with  $\text{Li}[\text{C}(\text{N}_2)\text{SiMe}_3]$  to form  $\text{L}_n\text{Rh}(\text{C}(\text{N}=\text{N})\text{SiMe}_3)$ . Photolysis of this product in benzene forms (79) ( $L = \text{PEt}_3$ ) through the proposed intermediates (80) and (81). It is suggested that (80) exists in the singlet state because of the stabilizing influence of the neighboring low-spin, electron-rich  $\{\text{RhL}_2\}$  unit, and as an electrophilic carbene, readily forms the ylide species (81).<sup>63</sup>

Mentioned in the previous edition<sup>1</sup> as a route to rhodium carbene complexes is the reaction of various low-valent complexes with electron-rich olefins like (**82**) ( $R = \text{Et}, \text{bz}$ ). Reaction of  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  with (**82**) forms the tris-carbene complex  $\text{Rh}(=\text{C}(\text{N}(\text{R})\text{CH}_2\text{CH}_2\text{N}(\text{R}))_3\text{Cl})$ , while with (**83**) the product is (**84**).<sup>64</sup> In related work, four equivalents of the imidazolium salt (**85**) ( $X = \text{Br}$ ;  $R = \text{bz}$ ) react with  $[\text{Rh}(\mu\text{-OEt})(\text{COD})]_2$ , prepared in situ from  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  and sodium ethoxide in ethanol to yield (**86**), and using the corresponding triazolium iodide, the same route furnishes (**87**), while with bis(diisopropylformamidinium)chloride the product is  $[\text{Rh}(=\text{C}(\text{NPr}^i)_2)\text{Cl}(\text{COD})]$ . The last can also be prepared from  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  and bis(diisopropylamino)carbene.<sup>65</sup> An alternate synthesis of (**86**) ( $X = \text{Cl}$ ;  $R = p\text{-tol}$ ) involves the reaction of (**85**) with silver oxide to form an intermediate silver imidazolium carbene complex and the reaction of this with  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$ . The COD ligand can be replaced by two carbonyl ligands. This work has been extended to the chiral oxazoline-substituted imidazolium salts (**88**) ( $R = \text{Me}, \text{Bu}^t$ ;  $R' = \text{Pr}^i, \text{bz}$ ), which on treatment with  $\text{LiOBu}^t$  and  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  in THF form (**89**). Chloride abstraction from (**89**) with  $\text{TIPF}_6$  then yields (**90**).<sup>66</sup> In related work, the bis(imidazolium) salts (**91**) ( $R = \text{Bu}^n$ ;  $X = \text{Br}$ ;  $Y = 1,2\text{-C}_6\text{H}_4$ ,  $R = \text{Pr}^i, \text{Bu}^n$ ;  $X = \text{I}$ ;  $Y = \text{CH}_2$ ) can be used to form (**92**) from  $\text{Rh}_2(\text{OAc})_4$  in acetonitrile ( $X = \text{I}$ ) or from  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$ , potassium iodide, and sodium acetate ( $X = \text{Br}$ ). The complexes function as catalyst precursors for the hydrogenation of  $\text{C}=\text{O}$  and  $\text{C}=\text{N}$  bonds via hydrogen transfer from isopropanol.<sup>67</sup> Treatment of (**91**) ( $R = \text{Bu}^n$ ;  $X = \text{Br}$ ;  $Y = 2,6\text{-C}_6\text{H}_3\text{N}$ ) with  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  and triethylamine forms (**93**) ( $Z = \text{RhBr}(\text{COD})$ ) which is a catalyst precursor for olefin hydroformylation (see *Carbonylation Processes by Homogeneous Catalysis*) and for which NMR studies indicate retention of the dinuclear structure under catalytic conditions.<sup>68</sup> Deprotonation of (**91**) ( $R = \text{Bu}^n$ ;  $X = \text{Cl}$ ;  $Y = 2,6\text{-}(\text{-CH}_2)\text{C}_6\text{H}_3\text{N}$ ) with silver oxide forms (**93**) ( $Z = \text{AgCl}$ ) and the  $\{\text{AgCl}\}$  units can be replaced by  $\{\text{RhCl}(\text{COD})\}$ .<sup>69</sup> In neither example of (**93**) does coordination of the pyridyl nitrogen to rhodium occur, but when (**94**) ( $R = \text{Pr}^i, \text{Bu}^n, \text{Bu}^t$ ) is reacted successively with  $[\text{Rh}(\mu\text{-Cl})(\text{COE})_2]_2$  and carbon tetrachloride, the product is (**95**) (see *Water & O-donor Ligands*) which contains a NCN “pincer” ligand (see also **5–8**). The water ligand can be replaced by an isocyanide ligand  $\text{CNR}'$  ( $R' = \text{CO}_2\text{Me}, \text{SO}_2(p\text{-tol})$ ) and this derivative in the presence of  $\text{KOBu}^t$ , undergoes an aldol condensation with aldehydes to form the carbene complex (**96**) ( $R'' = \text{Bu}^t, \text{Ph}$ ).<sup>70</sup>

Complexes of the type  $[\text{Cp}^*\text{Rh}(\text{R})(\mu\text{-CH}_2)]_2$  have been studied to probe details of the coupling of alkyl and methylene groups that could be relevant to mechanisms for the Fischer–Tropsch process (see *Organic Synthesis Using Metal-mediated Coupling Reactions*).<sup>71</sup> Reaction

of  $[\text{Cp}^*\text{Rh}(\text{vy})(\mu\text{-CH}_2)]_2$  with HCl forms  $\text{Cp}^*_2\text{Rh}_2\text{Cl}_2(\mu\text{-CH}_2)(\mu\text{-CHMe})$  via coupling of one vinyl and one methylene group. Alkylation of this species with Grignard reagents yields  $\text{Cp}^*_2\text{Rh}_2(\text{R})_2(\mu\text{-CH}_2)(\mu\text{-CHMe})$  ( $\text{R} = \text{Me}, \text{Et}, \text{vy}, \text{Bu}^n$ ), which proved to be thermally robust. Oxidative decomposition of the dimethyl complex forms methane, propene, and but-1-ene by the process proposed in equation (42) ( $\text{S} = \text{MeCN}$ ).<sup>72</sup>

In the complex  $\text{Cp}^*\text{Rh}(\text{CpCo})_2(\text{CO})_2(\mu\text{-CH}_2)$ , NMR studies indicate that the methylene group is quite mobile (see **Stability Constants & their Determination**) (equation 43) with the steps in which it moves

from a Rh–Co edge to the Co–Co edge thought to have a higher barrier than the other motions.<sup>72</sup>

## 2.5 Carbonyl Complexes

Carbonyl ligands are very prevalent in organometallic complexes of rhodium and may be either incidental to or

necessary for the formation of complexes (see **Carbonyl Complexes of the Transition Metals**) in which they are found. This section focuses primarily on carbonyl cluster complexes (see **Polynuclear Organometallic Cluster Complexes**) in which carbonyl groups are the sole or at least the primary ligands. DFT calculations (see **Molecular Orbital Theory**) on the unstable (in the absence of excess CO)  $\text{Rh}_2(\text{CO})_8$  molecule predict the lowest energy structure to be  $\text{Rh}_2(\text{CO})_6(\mu\text{-CO})_2$  of the  $\text{C}_{2v}$  symmetry, which is the same as observed for the cobalt analog although unbridged structures are not much higher in energy. The C–O stretching frequencies calculated from this model agree well with experiment.<sup>73</sup>

Structures of  $\text{Rh}_6(\text{CO})_{15}\text{L}$  complexes ( $\text{L} = \text{P}(\text{OPh})_3$ ,  $\text{PBU}_3^n$ ,  $\text{P}(4\text{-XC}_6\text{H}_4)_3$  ( $\text{X} = \text{CF}_3, \text{Cl}, \text{F}, \text{OMe}$ ), DMSO, MeCN, COE) have been determined and the structural effects of substitution are localized primarily in the vicinity of the substitution. In particular, in the triangle of rhodium atoms containing that bearing L, the Rh–Rh distances adjacent to the site of substitution are significantly lengthened and that opposite significantly shortened as compared to those remote from this site. This is attributed to an increase in electron density on the substituted metal as a result of substitution of CO by a ligand of lower  $\pi$ -acid character.<sup>74</sup> Heating of the fullerene (see **Carbon: Fullerenes**) derivative of  $\text{Rh}_6(\text{CO})_{16}$  formulated as  $\text{Rh}_6(\text{CO})_9(\text{DPPM})_2(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-C}_{60})$  with excess  $\text{C}_{60}$  in chlorobenzene followed by reaction with benzyliisocyanide leads to attachment of a second fullerene to the cluster and the product is  $\text{Rh}_6(\text{CO})_5(\text{DPPM})_2(\mu_3\text{-}\eta^2, \eta^2, \eta^2\text{-C}_{60})_2$ . The skeleton of the complex showing the locations of the fullerene substituents on opposite triangular faces of the metal octahedron is shown in (97). Cyclic voltammetric measurements show six well-separated, reversible, 1-electron reduction waves centered on the fullerene cages which are interpreted as the stepwise reduction to  $(\text{C}_{60})^- \text{Rh}(\text{C}_{60})$ ,  $(\text{C}_{60})^- \text{Rh}(\text{C}_{60})^-$ , and so on, implying an electronic communication between the cages (see **Electrochemistry: Applications in Inorganic Chemistry**). The complex is thus proposed to be a model for carbon nanotubes connected by a heterogeneous inorganic junction of potential future use in electronic materials.<sup>75</sup>

Reaction of  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  with *p*-toluidine and butyl lithium forms the tetrametallic imido cluster  $\text{Rh}_4(\mu\text{-NR})_2(\text{COD})_4$  ( $\text{R} = p\text{-tol}$ ) that is converted to  $\text{PPN}[\text{Rh}_3(\mu_3\text{-NR})_2(\text{CO})_6]$  on treatment with CO and then  $[\text{PPN}]\text{Cl}$ . Oxidation of the carbonyl cluster with one equivalent of ferricinium hexafluorophosphate yields  $[\text{Rh}_3(\mu_3\text{-NR})_2(\text{CO})_6]_2$  whose

skeleton is depicted in (98). This is thought to arise from the dimerization of  $[\text{Rh}_3(\mu_3\text{-NR})_2(\text{CO})_6]^-$  radicals formed by one-electron oxidation of the anionic trimetallic cluster.<sup>76</sup> One and two carbonyl ligands, respectively, in  $[\text{Rh}_5(\text{CO})_{15}]^-$  can be replaced by amines ( $\text{bzNH}_2$ ,  $\text{Ph}(\text{CH}_2)_3\text{NH}_2$ , pip) and diamines (en, pn, tn), while with  $\text{H}_2\text{N}(\text{CH}_2)_4\text{NH}_2$  ( $\text{L}_2$ ) some  $[\{\text{Rh}_5(\text{CO})_{14}\}_2(\mu\text{-L}_2)]^{2-}$  is seen in addition to  $[\text{Rh}_5(\text{CO})_{13}(\text{L}_2)]^-$ .<sup>77</sup>

Interest continues in the synthesis of heterobimetallic carbonyl clusters (see *Polynuclear Organometallic Cluster Complexes*) and most are prepared by the addition of carbonyl metallates to small- or medium-sized carbonyl clusters. For example, addition of four equivalents of  $[\text{HFe}(\text{CO})_4]^-$  to  $[\text{Rh}(\mu\text{-Cl})(\text{CO})_2]_2$  forms  $[\text{Fe}_2\text{Rh}(\text{CO})_{10}]^-$ , which is converted to (99) ( $\text{L} = \text{PPh}_3$ ) by addition of the phosphine. Similarly, two equivalents of  $[\text{Rh}(\text{CO})_4]^-$  added to  $\text{Fe}_2(\text{CO})_9$  followed by refluxing in acetone forms  $[\text{Fe}_2\text{Rh}_2(\text{CO})_{10}]^{2-}$ , which on reaction with  $[\text{Au}(\text{PPh}_3)]^+$  gives (100) ( $\text{L} = \text{PPh}_3$ ). Since  $[\text{Fe}_2\text{Rh}(\text{CO})_{10}]^-$  is a 46-electron cluster, it is coordinatively unsaturated which is reflected by its reactivity (equation 44). Combination of 2 mols of

$[\text{Rh}(\text{CO})_4]^-$  with 0.67 mol of  $\text{Ru}_3(\text{CO})_{12}$  gives  $[\text{Ru}_2\text{Rh}_2(\text{CO})_{12}]^{2-}$ , which on further reaction with 1.3 mols of  $\text{Ru}_3(\text{CO})_{12}$  forms (101). Oxidation of  $[\text{RuRh}_4(\text{CO})_{15}]^{2-}$

with iodine yields (102) plus  $[\text{Rh}(\mu\text{-I})(\text{CO})_2]_2$ .<sup>78</sup> Condensation of  $\text{Rh}_4(\text{CO})_{12}$  with  $\text{Pt}(\text{PPh}_3)_3$  provides a mixture of (103) and (104) ( $\text{L} = \text{PPh}_3$ ). Complex (104) is an electron-deficient 58-electron cluster. Also, condensation of  $[\text{Rh}(\text{CO})_4]^-$  with  $[\text{PtCl}(\mu\text{-DPPM})]_2$  in methanol in a CO atmosphere forms (105) (phenyl groups of DPPM omitted for clarity). The same species can also be obtained, but in lower yield, from the reaction of  $\text{Pt}_2(\text{CO})_3(\text{DPPM})_2$  and half an equivalent of  $\text{Rh}_4(\text{CO})_{12}$  under nitrogen in THF solution. Reaction of (105) with  $\text{Rh}_6(\text{CO})_{15}(\text{MeCN})$  forms  $\{\text{Rh}_6(\text{CO})_{14}\}(\mu\text{-CO})_2\{\text{Pt}_2\text{Rh}_2(\text{CO})_5(\text{DPPM})_2\}$  via displacement of the weakly bound acetonitrile. The complex is proposed to contain a donor metal-metal bond from the  $\text{Rh}_6$  unit to the  $\text{Rh}_2\text{Pt}_2$  unit. The related reaction of  $\text{Pt}_2(\text{CO})_3(\text{DPPM})_2$  directly with  $\text{Rh}_6(\text{CO})_{15}(\text{MeCN})$  at a low temperature followed by warming to room temperature gives  $\{\text{Rh}_6(\text{CO})_{14}\}(\mu\text{-CO})_2\{\text{Pt}_4(\text{DPPM})_3\}$ , where the skeleton is depicted as (106). In this instance, there is a dative metal-metal bond from platinum to rhodium.<sup>79</sup> A series of nickel/rhodium clusters have been prepared as indicated (equation 45) but most are

rather unstable, and all attempts to observe Lewis acid/base and redox properties failed because of decomposition.<sup>80</sup>

Rhodium/rhenium clusters have been prepared by combination of  $\text{RhCl}(\text{CO})(\text{PPh}_3)_2$  with  $[\text{Re}_2(\mu\text{-PR}_2)(\text{CO})_8]^-$  ( $\text{R} = \text{Ph}, \text{cy}$ ) under carbon monoxide and with  $\text{TlPF}_6$  as a halide abstraction agent. The initially obtained salt,  $[\text{Rh}(\text{CO})(\text{PPh}_3)_2][\text{Re}_2(\mu\text{-PR}_2)(\text{CO})_8]$ , loses a molecule of triphenylphosphine on standing in solution to give **(107)** ( $\text{L} = \text{PPh}_3$ ). If one starts with the preformed cationic rhodium complex  $[\text{Rh}(\text{COD})(\text{PPh}_3)_2]\text{BPh}_4$ , a redox condensation occurs with  $[\text{Re}_2(\mu\text{-PR}_2)(\text{CO})_8]^-$  in refluxing THF to form **(108)**, which is said to have a rhenium–rhodium double bond.<sup>81</sup>

## 2.6 Isocyanide Complexes

As in the preceding section, the emphasis of this section will be on rhodium complexes containing isocyanide ligands, wherein the isocyanide ligand is the particular focus of the report. For example, there has been an extensive study of the spectroscopic and luminescent properties (see *Luminescence Behavior & Photochemistry of Organotransition Metal Compounds* and *Electronic Structure of Organometallic Compounds*) of **(109)** ( $\text{L} = \text{CNBu}^t$ ,  $\text{X} = \text{Pt}(\text{CN})_2$ ;  $n = 1$ .  $\text{X} = \text{Ag}, \text{Au}$ ;  $n = 2$ ). All show an intense singlet  $d\sigma^* \rightarrow p\sigma$  absorption and molecular orbital calculations indicate that the  $d\sigma^*$  orbital is mainly  $\text{Rh } 4d_{z^2}$  in character while the  $p\sigma$  orbital is a combination of isocyanide  $\pi^*$  and  $\text{Rh } 5p_z$  character. The absorption band therefore has significant  $\text{Rh} \rightarrow \pi^*$  charge transfer character. All complexes are phosphorescent.<sup>82</sup> Thermodynamic parameters for the disproportionation of the mixed-valence dimers  $[\text{Rh}_2(\mu\text{-L}_2)_{4-n}(\mu\text{-DPPM})_n]^{3+}$  ( $\text{L}_2 =$

$\text{TM4}$ ,  $n = 0$ ;  $\text{L}_2 = \text{dimen}$ ;  $n = 0-2$ ;  $\text{L}_2 = \text{bridge}$ ;  $n = 2$ ) have been described and it appears that only when no DPPM ligands are present is this a facile process. The large difference in the tendency to disproportionate between this complex and those containing one or more DPPM ligands is attributed to large differences in the energies of the oxidized species within the series relative to those of the mixed-valence starting complexes. These energy differences are largely governed by the different affinities of the oxidized species for axial ligands as a function of the extent of substitution of diisocyanide ligands by DPPM.<sup>83</sup>

Addition of aryl azides to  $\text{CpRh}(\text{PMe}_3)(\text{CNMe})$  results in coupling of the aryl nitrene with the isocyanide to form **(110)** ( $\text{Ar} = \text{Ph}, p\text{-tol}$ ) which can be converted to **(111)** ( $\text{R}' = \text{H}, \text{Me}$ ), another example of a carbene complex (see also **73**, Section 2.4, *Carbene Complexes*).<sup>84</sup> Replacement of COD in  $\text{Rh}_2(\text{COD})_2(\mu\text{-Cl})(\mu\text{-PBu}^t_2)$  by *t*-butylisocyanide yields  $\text{Rh}_2(\text{CNBu}^t)_4(\mu\text{-Cl})(\mu\text{-PBu}^t_2)$ , which on treatment with one equivalent of lithium di(*t*-butyl)phosphide forms  $[\text{Rh}(\text{CNBu}^t)_2(\mu\text{-PBu}^t_2)]_2$ , which has a planar  $\text{Rh}_2\text{P}_2$  core and no  $\text{Rh}\text{--}\text{Rh}$  bond. In a chloroform solution, the last complex is slowly converted into a mixture of *cis*- and *trans*- $[\text{RhCl}(\text{CNBu}^t)(\mu\text{-PBu}^t_2)]_2$ , while oxidation with ferricinium hexafluorophosphate yields  $\{[\text{Rh}(\text{CNBu}^t)_2(\mu\text{-PBu}^t_2)]_2\}^{2+}$ . Both of the oxidized dimers contain  $\text{Rh}\text{--}\text{Rh}$  bonds.<sup>85</sup>

Cleavage of the chloride bridges in  $[\text{Cp}^*\text{RhCl}(\mu\text{-Cl})]_2$  by 1,4-diisocyanobenzenes yields  $\{\text{Cp}^*\text{RhCl}_2\}_2(\mu\text{-CN-R-NC})$  ( $\text{R} = 2,3,5,6\text{-Me}_4\text{C}_6$ ;  $2,5\text{-Me}_2\text{C}_6\text{H}_2$ ). Abstraction of one chloride ligand from each metal by silver triflate is followed by condensation of two of the resulting dications to form the metallamacrocycle **(112)**. The larger cavity species **(113)** ( $\text{X} = \text{CN-R-NC}$ , 4,4'-bipyridyl) can be obtained by a second bridge-splitting reaction on **(112)** (see also Section 4.2).<sup>86</sup>

### 3 COMPOUNDS OF LIGANDS CONTAINING LOCALIZED $\pi$ -BONDS

#### 3.1 Complexes of Alkenes

Synthetic routes to alkene complexes remain primarily the same as in the preceding edition, but there has been significant interest shown in forming isolable complexes containing an alkene and either a hydride or an alkyl ligand, in order to study migratory insertions (see *Oligomerization & Polymerization by Homogeneous Catalysis* and *Organic Synthesis Using Metal-mediated Coupling Reactions*). An interesting three-coordinate alkene complex, (115), results from the treatment of  $[\text{Rh}(\mu\text{-Cl})(\text{COE})_2]_2$  with (114) ( $\text{Ar} = 2,6\text{-X}_2\text{C}_6\text{H}_3$  ( $\text{X} = \text{Me}, \text{Cl}$ )), although when  $\text{X} = \text{Cl}$ , there is an agostic interaction of one chlorine substituent with the metal to relieve the coordinative unsaturation. Complex (115) ( $\text{X} = \text{Me}$ ) adds dinitrogen and oxidatively adds dihydrogen. A low-temperature NMR study indicates the formation of a dihydrogen adduct (see *Hydrogen Bonding & Dihydrogen Bonding*) prior to the generation of the dihydride species. The same complex is a catalyst for alkene hydrogenation (see *Hydrogenation & Isomerization of Alkenes*) and the rate-determining step is considered to be either the conversion of the dihydrogen adduct to the dihydride or the migratory insertion of the alkene. Presumably, the combined bulk of the diimine and COE ligands permits the isolation of the three-coordinate (115), since with  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  and  $[\text{Rh}(\mu\text{-Cl})(\text{C}_2\text{H}_4)_2]_2$ , four-coordinate products are obtained.<sup>87</sup> In related work, (116) ( $\text{Ar} = 2,6\text{-Pr}^i_2\text{C}_6\text{H}_3$ ) reacts with  $[\text{Rh}(\mu\text{-Cl})(\text{C}_2\text{H}_4)_2]_2$  followed by treatment with  $\text{NaBAR}_f$  (see *Boron: Organoboranes*) in the presence of ethylene to form (117). This oxidatively adds methyl iodide (see *Carbon–Carbon & Carbon–Heteroatom Activation*) and subsequent abstraction of iodide with  $\text{AgBF}_4$  in the presence of ethylene forms the cationic alkyl olefin complex (118), which was detected spectroscopically but not isolated in pure form. No evidence was found for ethylene polymerization (see *Oligomerization & Polymerization by Homogeneous Catalysis*) in this system (presumably migratory insertion of ethylene into the Rh–methyl bond would be the initial step) in contrast to related systems containing the Cn-type ligands (see

Section 2.1). The difference in reactivity between the two was attributed to the mer coordination of the supporting ligand here in contrast to the fac coordination of the Cn ligands.<sup>88</sup> Some success in facilitating alkene oligomerization (see *Organic Synthesis Using Metal-mediated Coupling Reactions*) was realized with  $\text{Tp}'\text{Rh}(\text{C}_2\text{H}_4)_2$  (see also Reference 18). Heating the solid compound at  $60^\circ\text{C}$  forms a mixture of *exo*- and *endo*- $\text{Tp}'\text{Rh}(\text{H})(\eta^3\text{-C}_3\text{H}_4\text{Me})$ , which on photolysis converts to the butadiene complex  $\text{Tp}'\text{Rh}(\eta^2; \eta^2\text{-CH}_2=\text{CHCH}=\text{CH}_2)$ . This last complex can also be generated, together with ethane from the reaction of  $\text{Tp}'\text{Rh}(\text{C}_2\text{H}_4)_2$  with ethylene at room temperature, but if this is done at  $-40^\circ\text{C}$ , the complexes  $\text{Tp}'\text{Rh}(\text{Et})(\eta^3\text{-C}_3\text{H}_4\text{Me})$  and  $\text{Tp}'\text{Rh}(\eta^2; \eta^2\text{-CH}_2=\text{CHCH}=\text{CHC}_2\text{H}_5)$  are also seen. The formation of the C–C coupling products is proposed to be initiated by the conversion of an ethylene ligand into a vinyl hydride complex (see also equation 9, section 2.1).<sup>89</sup> Protonation of  $(\text{acac})\text{Rh}(\text{C}_2\text{H}_4)_2$  with triflic acid in THF solution forms, predominantly,  $(\text{acac})\text{Rh}(\text{C}_2\text{H}_5)$ , which was not isolated and is presumably solvated. Some but-2-enes were also detected implicating ethylene insertion into the Rh–Et bond, but no ethylene polymerization was detected. It is proposed that the putative rhodium–butyl complex undergoes  $\beta$ -hydride elimination with subsequent butene displacement by ethylene faster than the ethylene can insert into the rhodium–butyl bond.<sup>90</sup>

The calix[4]arene-based diphosphine (119) ( $\text{R} = \text{Me}, \text{Pr}^i$ ,  $\text{Ph}$ ;  $\text{R}' = \text{Pr}^i$ ) on reaction with  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  and then  $\text{TIPF}_6$  forms the dinuclear species (120). These were tested as catalysts for hex-1-ene hydroformylation (see *Carbonylation Processes by Homogeneous Catalysis*) and that with  $\text{R} = \text{Ph}$  was best, but the performance was not better than extant systems and no special role for the calixarene moieties could be discerned.<sup>91</sup> Several papers have used DFT calculations as part of QM/MM studies (see *Molecular Orbital Theory*) to probe the course of the hydroformylation process (see *Carbonylation Processes*

by *Homogeneous Catalysis*) catalyzed by  $\text{Rh(H)(CO)L}_3$  (L = tertiary phosphine) complexes with particular emphasis on the origin of the regioselectivity (straight vs. branched chain aldehyde). There are, however, enough differences between the models used and/or the restrictions on them that comparisons between the results are not easy to make. The first used  $\text{Rh(H)(CO)(alkene)(PH}_3)_2$  to model the migratory insertion of ethylene and propylene into the Rh bond and the DFT-derived geometries with fixed coordination spheres were used in the MM stage with  $\text{L} = \text{PPh}_3$  to model real systems based on diphosphine ligands. Reasonable predictions for the observed regioselectivities were provided by this model. The use of rigid coordination spheres in the MM stage has been criticized in a second study, which also begins with DFT calculations on  $\text{Rh(H)(CO)(alkene)(PH}_3)_2$  but uses (121) ( $\text{X} = \text{PPh, SiMe}_2, \text{S, CMe, C}=\text{CMe}_2, \text{NR, (CH}_2)_2$ ) as the ligand in the MM stage. It is concluded that here the regioselectivity is governed primarily by nonbonding interactions between the phenyl groups on phosphorus and the alkene. Changes in the “bite” angle of the diphosphine seem to have little effect. The most extensive study again used  $\text{Rh(H)(CO)(C}_2\text{H}_4)(\text{PH}_3)_2$  for the QM portion and the sequence of equation (46) was proposed as the lowest energy path for the catalytic cycle. The results suggest that the migratory insertion of the carbonyl and ethyl groups is the rate-determining step, although experimentally it is thought that the oxidative addition of dihydrogen is rate-determining. Another peculiarity is the predicted generation of *cis*- $\text{Rh(H)(CO)L}_2$  following reductive

elimination of aldehyde and the determination that cycles beginning with this isomer are energetically less favorable than those shown above. To explain this, it is suggested that the alkene adduct of *cis*- $\text{Rh(H)(CO)L}_2$  could undergo a Berry pseudorotation to generate the isomer shown at the top right of equation (46). These studies were extended to explore the alkene insertion steps for propylene where regiochemical

information could be obtained. The possible conformations found for the transition states for propylene insertion are (122) and (123), with the former on the path to the linear product while the latter is on the path to the branched isomer. Both equatorial–equatorial ( $\text{X} = \text{CO; Y} = \text{P}$ ) and axial–equatorial ( $\text{X} = \text{P; Y} = \text{CO}$ ) propylene adduct precursors to these transition states were also examined with the conclusion that the axial–equatorial isomer predominated by a factor of 3 but that the equatorial–equatorial isomer was 15 times reactive. There are therefore two channels predicted for the hydroformylation process: linear aldehyde from the less reactive but more abundant alkene adduct through (122) ( $\text{X} = \text{P; Y} = \text{CO}$ ) and branched product from the more reactive minor adduct through (123) ( $\text{X} = \text{CO; Y} = \text{P}$ ). The experimentally observed regioselectivities are suggested to arise from ground-state discrimination between the two most stable isomers of the alkene adduct, and therefore, to be particularly sensitive to the steric profile of the phosphine ligands. This question was explored, unfortunately only with ethylene, in MM calculations on  $\text{Rh(H)(CO)(C}_2\text{H}_4)\text{L}_2$  ( $\text{L} = \text{PMe}_3, \text{PPh}_3, \text{P}(m\text{-XC}_6\text{H}_4)_3, \text{P}(p\text{-XC}_6\text{H}_4)_3$  ( $\text{X} = \text{SO}_3^-$ )). For all the aryl phosphine ligands, the presence of the aryl substituents renders the equatorial–equatorial transition state (cf. 122) ( $\text{X} = \text{CO; Y} = \text{P}$ ) more favorable and because of  $\pi$ -stacking interactions, the insertion product *cis*- $\text{Rh(Et)(CO)L}_2$  is preferred to the *trans* isomer.<sup>92</sup> Related DFT calculations on  $\text{Rh(H)(CO)}_3(\text{CH}_2=\text{CHMe})$  predict the most stable isomer to be the one having the alkene lying in the equatorial plane of the trigonal bipyramidal coordination sphere. From this, the calculated lowest energy path to aldehyde gives a ratio of linear to branched product comparable to that found experimentally, when  $\text{Rh}_4(\text{CO})_{12}$  is the catalyst precursor ( $\text{Rh(H)(CO)}_3(\text{CH}_2=\text{CHMe})$  is the presumed alkene adduct formed in the catalytic cycle). Polarizable and/or electron-withdrawing substituents on the alkene are predicted to favor branched product while bulky substituents favor the linear isomer.<sup>93</sup>

One computational study (see *Molecular Orbital Theory*) has appeared using  $\{\text{RhCl}(\text{PH}_3)_2\}$  to model the rhodium-catalyzed hydroboration of ethylene (see *Hydroboration Catalysis*). Both associative and dissociative pathways were examined (equation 47). In the associative path, three possible

been the subject of several studies, both experimental and computational. The use of para-hydrogen-induced-polarization in the  $\text{RhCl}(\text{PPh}_3)_3$ -catalyzed hydrogenation of hex-1-ene and related alkenes demonstrated the presence of several species, heretofore, undetected. Two of these are (124) and (125). The latter is detected when the alkene is styrene or its derivatives, while the former is determined not to be in the catalytic cycle and so represents a path lowering the catalyst activity. Its formation can be inhibited by the presence of small amounts of free phosphine.<sup>96</sup> The factors responsible for the high enantioselectivity in the hydrogenation of prochiral alkenes (*see Asymmetric Synthesis by Homogeneous Catalysis*), particularly (Z)- $\alpha$ -acetamidocinnamate esters catalyzed by cationic rhodium complexes of diphosphines have been explored by NMR and computational methods. There appears, from these results, to be considerable conformational mobility of the metal-complexed alkene so that a rigid chiral template is not established by the metal diphosphine framework. Instead, the primary enantiodiscriminating interaction is that between the plane of the enamide ester functionality and the proximal arene ring of the ligand. Molecular mechanics calculations were able to account for the diastereoselectivity of alkene binding but not the relative reactivities of the oxidative adducts of the alkene complexes with dihydrogen. This latter feature has been previously shown to be critical in determining the enantiomeric excess produced in the product. Some of the computational work suggested the possible importance of species such as (126) in the catalytic cycle.<sup>97</sup>

intermediates were considered to be on the reaction coordinate.<sup>94</sup> A related study on the hydrosilylation of alkenes (*see Hydrosilylation Catalysis*) using  $\text{RhCl}(\text{PH}_3)_3$  as a catalyst model supports the modified Chalk–Harrod mechanism, namely oxidative addition of the Si–H bond to the metal followed by alkene coordination, insertion of the alkene into the Rh–Si bond, and C–H reductive elimination.<sup>95</sup>

The rhodium-catalyzed hydrogenation of alkenes (*see Hydrogenation & Isomerization of Alkenes*) has also

The classical Dewar–Chatt–Duncanson model for metal–alkene bonding has been revisited with a combination of X-ray structural data (*see Diffraction Methods in Inorganic Chemistry*) and DFT calculations (*see Molecular Orbital Theory*), particularly on complexes of the type  $(\text{acac})\text{Rh}(\text{alkene})_2$ . These indicate the existence of distortions from idealized geometry involving a “twist” (127), where the axis of the double bond is no longer perpendicular to the molecular plane and a “roll” (128), where the line

joining the midpoint of the double bond to the metal is no longer in the molecular plane. The latter distortion is seen for unsymmetrically substituted alkenes and occurs so as to place the more nucleophilic carbon atom closer to the molecular plane.<sup>98</sup> The coordination geometries of (acac)Rh(C<sub>2</sub>H<sub>4</sub>)<sub>2</sub> and its hfac analog determined by X-ray structure analysis (see *Diffraction Methods in Inorganic Chemistry*) are reproduced satisfactorily by DFT calculations. Similar calculations to determine <sup>103</sup>Rh chemical shifts in (acac)Rh(alkene)<sub>2</sub> complexes also agree well with experiment and with a correlation found previously between these chemical shifts and stability constants for these monoalkene complexes. Chelating and fluorinated alkenes do not follow this correlation presumably because of the chelate effect in the former and bonding more akin to a metallacyclopropane in the latter.<sup>99</sup>

(127)

(128)

The complex [Cp\*Rh(CH<sub>3</sub>)(μ-CH<sub>2</sub>)<sub>2</sub>Rh(L)Cp\*]PF<sub>6</sub> (L = η<sup>2</sup>-C<sub>2</sub>H<sub>4</sub>) has been synthesized from the analog with L = MeCN by ligand exchange and obtained as a 2:1 mixture of trans and cis isomers. Decomposition above room temperature formed mainly methane and ethylene and small to trace amounts of ethane and propylene.<sup>100</sup> As another example that water is not necessarily incompatible with organotransition metal compounds (see *Water & O-donor Ligands*), the complexes [Rh(L<sub>2</sub>)(H<sub>2</sub>O)<sub>2</sub>]OTs (L<sub>2</sub> = COD, NBD, CH<sub>2</sub>=C(Me)CH=CH<sub>2</sub>, CH<sub>2</sub>=C(Me)C(Me)=CH<sub>2</sub>, (C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>) have been prepared from [Rh(μ-Cl)(L<sub>2</sub>)<sub>2</sub>] and silver tosylate in water.<sup>101</sup> The unsubstituted double bond in mono-aryl allenes coordinates to rhodium in four-coordinate *trans*-RhClL<sub>2</sub>(H<sub>2</sub>C=C=CHAr) and five-coordinate RhClL<sub>3</sub>(H<sub>2</sub>C=C=CHAr) (L = PMe<sub>3</sub>; Ar = Ph, *p*-FC<sub>6</sub>H<sub>4</sub>) (cf. **39**, **45**) which are prepared, respectively, from [Rh(μ-Cl)L<sub>2</sub>]<sub>2</sub> or RhClL<sub>3</sub> and approximately stoichiometric quantities of the allene. Particularly in the four-coordinate complex, there is an agostic interaction of an ortho hydrogen on the aryl group with a metal. If three equivalents of the allene are reacted with RhClL<sub>3</sub>, coupling of two allene molecules occurs to form (129).<sup>102</sup> The unsymmetrical ligand R<sub>2</sub>PCH<sub>2</sub>SbR<sub>2</sub> (R = Pr<sup>i</sup>) cleaves the chloride bridge in [Rh(μ-Cl)(COD)]<sub>2</sub> to form RhCl(COD)(R<sub>2</sub>PCH<sub>2</sub>SbR<sub>2</sub>) where the ligand coordinates only via phosphorus. Chelation can be achieved by abstraction of the chloride by AgPF<sub>6</sub>, and addition of diazomethane to the resulting cationic complex forms (130) instead of the desired carbene complex.<sup>103</sup>

(129)

(130)

### 3.2 Complexes of Alkynes

Simple alkyne complexes continue to be reported, but the primary interest is in systems where the alkyne is transformed either by rearrangements (see Section 2.4 for conversion to vinylidenes and allenylidenes) or by coupling reactions between alkynes and/or other coordinated ligands (see *Organic Synthesis Using Metal-mediated Coupling Reactions*). Terminal alkynes cleave a Co–Co bond in Rh<sub>n</sub>Co<sub>3–n</sub>(CO)<sub>12</sub> (*n* = 1, 2) to form the butterfly clusters Rh<sub>n</sub>Co<sub>3–n</sub>(CO)<sub>6</sub>(μ-CO)<sub>4</sub>(μ<sub>4</sub>,η<sup>2</sup>-HC≡CR) (R = CpFe(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>), CH<sub>2</sub>OH, MeOC<sub>10</sub>H<sub>6</sub>C(HMe)C(O)OCH<sub>2</sub>) (see *Polynuclear Organometallic Cluster Complexes*).<sup>104</sup>

The final product of the reaction of alkynes (PhC≡CH, PhC≡CPh, DMAD, HFB, HC≡CCO<sub>2</sub>Me) with Cp\*Rh(PMe<sub>3</sub>)H<sub>2</sub> is the corresponding alkene complex Cp\*Rh(PMe<sub>3</sub>)(η<sup>2</sup>-alkene) formed by hydrogenation of the C≡C bond. In the cases of HFB and methyl propiolate, intermediate vinyl hydride complexes could be detected.<sup>105</sup> Triethylgermane undergoes oxidative addition to (acac)Rh(COE)(Pcy<sub>3</sub>) to form (131) (Y = GeEt<sub>3</sub>; L = Pcy<sub>3</sub>), which effects hydrogermylation (see *Germanium: Organometallic Chemistry*) of terminal alkynes to yield (132) (R = CO<sub>2</sub>Me, Ph). Complex (131) (Y = SnPh<sub>3</sub>) is similarly obtained from triphenylstannane but only the hydride ligand can be transferred to an alkyne and (133) (R = CO<sub>2</sub>Me, Ph) results. The difference is attributed to the greater strength of a C–Ge bond over a C–Sn bond coupled with the Rh–Sn bond being stronger than a Rh–Ge bond.<sup>106</sup> Aryl phosphines containing *o*-methoxy groups are often *O*-demethylated on reaction with transition metal complexes and this occurs in the reaction of [Cp\*Rh(μ-Cl)Cl]<sub>2</sub> with PPh<sub>n</sub>(2,6-(MeO)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>3–n</sub> (*n* = 1, 2) to form (134) (R' = Ph, 2,6-(MeO)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>). Alkyne coupling occurs with terminal alkynes (PhC≡CH, *p*-tolC≡CH) to give (135) (R' = Ph; R<sub>1</sub> = R<sub>4</sub> = Ph, *p*-tol; R<sub>2</sub> = R<sub>3</sub> = H), while with R''C≡CCO<sub>2</sub>R, the product is (136) (R' = Ph, R = Me, Et; R'' = H, R = Me, R'' = CO<sub>2</sub>Me).<sup>107</sup> Cou-

(131)

(132)

(133)

pling of methyl propiolate with one of the bridging thiolate ligands (see **Tellurium: Organotellurium Chemistry**) in  $[\text{Cp}^*\text{Rh}(\mu\text{-Cl})(\mu\text{-SPr}^i)_2]\text{OTf}$  yields (137) ( $\text{R} = \text{CO}_2\text{Me}$ ), while  $\text{HC}\equiv\text{C}(\text{CH}_2)_2\text{OH}$  forms the cyclic carbene (138).<sup>108</sup>

Complex (139) is prepared from  $[\text{Rh}(\mu\text{-Cl})(\text{CO})_2]_2$  and a Cn derivative (**1** ( $\text{R} = -(\text{CH}_2)_3\text{C}\equiv\text{CMe}$ ; Section 2.1)) by standard methods. Either thermal or photochemical conditions cause coupling of two alkynyl arms with a carbonyl group (see **Organic Synthesis Using Metal-mediated Coupling Reactions**) to yield (140).<sup>109</sup> Cyclization with metallacycle formation (see **Organic Synthesis Using Metal-mediated Coupling Reactions**) occurs when the diyne  $\text{O}(\text{CH}_2\text{C}\equiv\text{CCO}_2\text{Me})_2$  is reacted with the Rh(I) chloro complex of the bis(oxazoline) ligand (141) to yield (142),<sup>110</sup> while acidification of the dinuclear acetylide complex  $[\text{Cp}^*\text{Rh}(\text{C}\equiv\text{CR})(\mu\text{-CH}_2)_2]$  ( $\text{R} = \text{Ph}$ , *p*-tol) with  $\text{HBF}_4$  initiates coupling of both acetylide ligands with the methylenide groups (see **Organic Synthesis Using Metal-mediated Coupling Reactions**) to give (143) ( $\text{X} = \text{H}$ , Me) together with its anti isomer. Since  $\text{HCl}$  merely cleaves the acetylide ligand from  $[\text{Cp}^*\text{Rh}(\text{C}\equiv\text{CR})(\mu\text{-CH}_2)_2]$ , the formation of (143) appears to require the presence of a noncoordinating anion and it is proposed that the reaction may proceed through (144) and (145) as intermediates although no vinylidene species could be detected even at a low temperature. In this instance, one alkynyl unit couples with one methylene unit but when phenyl acetylene reacts with

$[\text{Cp}^*\text{Rh}(\text{MeCN})(\mu\text{-CH}_2)_2]^{2+}$ , both methylene units couple with two alkyne molecules (see **Organic Synthesis Using Metal-mediated Coupling Reactions**) to form (146).<sup>111</sup>

A considerable number of reactions of  $\text{CpRh}(\mu\text{-CO})(\mu\text{-}\eta^2\text{:}\eta^2\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{RhCp}$  have been reported which illustrates the diversity of products that can be obtained in transition metal alkyne chemistry (see **Organic Synthesis Using Metal-mediated Coupling Reactions**). Reaction of this complex with dimethyldiazomethane forms a mixture of (147) and (148), and on recrystallization (148) converts to (149) by

a 1,4 hydrogen shift. By contrast,  $\text{CpRh}(\mu\text{-CO})(\mu\text{-}\eta^2\text{:}\eta^2\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{RhCp}$  with  $\text{N}_2\text{C}(\text{CO}_2\text{Me})_2$  forms **(150)** ( $\text{R} = \text{CO}_2\text{Et}$ ) where the alkylidene unit couples with the alkyne to form **(151)**. The formation of **(147)**, one of a number of examples of the complexation of intact diazoalkanes, is taken to indicate that the first step of both reactions is coordination of the diazoalkane to the metal via nitrogen, with the subsequent course of the reaction being determined by both steric and electronic factors. Attempts to couple  $(\text{CpMe})\text{Mn}(\text{CO})_2(\text{THF})$  (see *Manganese: Organometallic Chemistry*) with  $\text{CpRh}(\mu\text{-CO})(\mu\text{-}\eta^2\text{:}\eta^2\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{RhCp}$  in a photolytic reaction led instead to cleavage of the methylcyclopentadienyl ligand from manganese and the formation of **(152)**.<sup>112</sup> The alkynyl phosphines  $\text{Ph}_2\text{PC}\equiv\text{CR}$  ( $\text{R} = \text{Me}, \text{Ph}$ ) act as simple phosphine ligands ( $\text{L}$ ) toward  $\text{CpRh}(\mu\text{-CO})(\mu\text{-}\eta^2\text{:}\eta^2\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{RhCp}$  to form  $\text{CpRh}(\text{CO})(\mu\text{-}\eta^1\text{:}\eta^1\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{Rh}(\text{L})\text{Cp}$ , but on treatment of the initial product with alumina in the presence of oxygen, alkyne coupling occurs to form **(153)**.<sup>113</sup> In a similar fashion,  $\text{CpRh}(\text{CO})(\mu\text{-}\eta^1\text{:}\eta^1\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{Rh}(\text{L})\text{Cp}$  ( $\text{L} = \text{SRR}'$  ( $\text{R} = \text{R}' = \text{Me}, \text{Et}, \text{Pr}^n, \text{bz}$ ;  $\text{R} = \text{Me}$ ;  $\text{R}' = \text{Et}$ ) is formed with the addition of one equivalent of the disulfide, but when these products ( $\text{R} = \text{R}' = \text{Me}, \text{Et}$ ) are reacted with more of the same disulfide, **(154)** ( $\text{R}'' = \text{Et}, \text{Bu}^s$ ) is formed in a metal-mediated Stevens rearrangement.<sup>114</sup> Complex **(155)** is formed from  $\text{CpRh}(\text{CO})(\mu\text{-}\eta^1\text{:}\eta^1\text{-F}_3\text{CC}\equiv\text{CCF}_3)\text{Rh}(\text{L})\text{Cp}$  ( $\text{L} = \eta^1\text{-DPPE}$ ) and  $\text{CpPd}(\eta^3\text{-C}_3\text{H}_5)$ .<sup>115</sup>

The reaction of  $\text{RhCl}(\text{PMe}_3)_3$  with  $\text{Li}(\text{THF})_3[\text{Si}(\text{SiMe}_3)_3]$  in the presence of alkynes leads to Si-C coupling and

metallacycle formation (equation 48 ( $\text{L} = \text{PMe}_3$ ;  $\text{R} = \text{Me}, \text{Ph}$ )). It is proposed that  $\text{L}_3\text{Rh}(\text{Si}(\text{SiMe}_3)_3)$  is formed initially and is converted to the

silylene complex shown at the top left of equation (48) by a 1,2 migration of a trimethylsilyl group.<sup>116</sup>

As has been demonstrated repeatedly in the past, the reaction of alkynes with coordinatively unsaturated metal complexes frequently leads to a plethora of products resulting from the coupling of two or more alkyne molecules, sometimes also with inclusion of molecules present as ligands on the starting complex (see *Organic Synthesis Using Metal-mediated Coupling Reactions*). Treatment of  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  with  $\text{Pr}^n\text{Li}$  and but-2-yne forms **(156)** ( $\text{R} = \text{Me}$ ), but photolysis of  $\text{CpRh}(\eta^2\text{-C}_2\text{H}_4)_2$  with  $\text{RC}\equiv\text{CR}$  ( $\text{R} = \text{Me}, \text{Et}$ ) yields  $\text{CpRh}(\eta^2\text{-RC}\equiv\text{CR})(\eta^2\text{-C}_2\text{H}_4)$ ,  $\text{CpRh}(\eta^4\text{-C}_6\text{R}_6)$ , and **(157–160)** among other species. The oxygen atom in **(159)** is considered to result from hydrolysis during chromatographic workup of the crude reaction mixture while the formation of **(160)** suggests the intermediacy of a vinyl hydride species as has been found in the related  $\text{Tp}'$  and  $\text{Cn}$  systems (see Section 2.1).<sup>117</sup> Coupling of a

coordinated alkyne with an isocyanide occurs when  $\text{CpRh}(\eta^2\text{-PhC}\equiv\text{CPh})(\text{SbPr}_3^i)$  with one equivalent of methyl isocyanide and (161) is formed. This reacts with a further two equivalents of an isocyanide to give the double insertion product (162) ( $\text{R} = \text{Me}, \text{Bu}^t$ ).

Complex (162) ( $\text{R} = \text{Me}$ ) can be obtained directly from  $\text{CpRh}(\eta^2\text{-PhC}\equiv\text{CPh})(\text{SbPr}_3^i)$  and three equivalents of methyl isocyanide.<sup>118</sup>

Considerable use has been made of  $[\text{Pt}(\text{C}\equiv\text{CR})_4]^{2-}$  ( $\text{R} = \text{Bu}^t, \text{SiMe}_3$ ) and  $\text{cis}[(\text{C}_5\text{F}_5)_2\text{Pt}(\text{C}\equiv\text{CR})_2]^{2-}$  ( $\text{R} = \text{Bu}^t, \text{Ph}, \text{SiMe}_3$ ) for the construction of multimetallic complexes via coordination of other metals to the C–C triple bonds. Thus,  $[\text{Pt}(\text{C}\equiv\text{CR})_4]^{2-}$  with  $[\text{Rh}(\text{COD})(\text{acetone})_2]^+$  forms (163) ( $\text{R} = \text{Bu}^t, \text{SiMe}_3$ ), while  $\text{cis-M}(\text{C}_6\text{F}_5)_2(\text{THF})_2$  ( $\text{M} = \text{Pd}, \text{Pt}$ ) reacts with  $\text{Cp}^*\text{Rh}(\text{X})(\text{C}\equiv\text{CR})(\text{PEt}_3)$  to give (164) ( $\text{X} = \text{Cl}, \text{C}\equiv\text{CR}$ ;  $\text{R} = \text{Bu}^t, \text{Ph}$ ;  $\text{R}' = \text{C}_6\text{F}_5$ ;  $\text{M} = \text{Pd}, \text{Pt}$ ). Further reaction of (164) with an excess of

$[\text{M}'(\text{C}\equiv\text{CPh})]_n$  ( $\text{M}' = \text{Cu}, \text{Ag}$ ) forms (165). Similarly,  $\text{cis}[(\text{C}_5\text{F}_5)_2\text{Pt}(\text{C}\equiv\text{CR})_2]^{2-}$  and  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  give (166) while with  $[\text{Rh}(\text{COD})(\text{Et}_2\text{O})_x]^+$  the bimetallic complex (167) is formed. Finally, acetylide ligand transfer from  $[\text{Pt}(\text{C}\equiv\text{CR})_4]^{2-}$  ( $\text{R} = \text{Bu}^t, \text{SiMe}_3$ ) to rhodium occurs in its reaction with  $[\text{Cp}^*\text{Rh}(\text{PEt}_3)(\text{acetone})_x]^{2+}$  and the product is (168) ( $\text{L} = \text{PEt}_3$ ). Reaction of (168) with one equivalent of  $\text{cis-Pt}(\text{C}_6\text{F}_5)_2(\text{THF})_2$  attaches a  $\{\text{cis-Pt}(\text{C}_6\text{F}_5)_2\}$  fragment to the two acetylide ligands attached to Pt.<sup>119</sup>

## 4 COMPOUNDS OF LIGANDS CONTAINING DELOCALIZED $\pi$ -BONDS

### 4.1 Allyl Complexes

Oxidative addition of allyl bromide (see **Carbon–Carbon & Carbon–Heteroatom Activation**) to  $\text{Tp}'\text{Rh}(\text{COE})(\text{MeCN})$  initially yields  $\text{Tp}'\text{Rh}(\eta^1\text{-CH}_2\text{CH}=\text{CH}_2)(\text{Br})(\text{MeCN})$  but on heating in benzene solution it converts into  $\text{Tp}'\text{Rh}(\eta^3\text{-C}_3\text{H}_5)\text{Br}$ . This is an example of a typical procedure for the formation of  $\eta^3$ -allyl complexes, where the  $\eta^1$ -allyl complex is formed via oxidative addition of an allyl halide to a low-valent metal center or by metathesis of a metal halogen

bond with an allyl Grignard or lithium reagent. Loss of a relatively labile two-electron donor ligand via thermolysis or photolysis converts the one-electron donor  $\eta^1$ -allyl ligand to a three-electron donor  $\eta^3$ -allyl ligand. Despite NMR evidence for significant electron deficiency in the allyl group in  $\text{Tp}'\text{Rh}(\eta^3\text{-C}_3\text{H}_5)\text{Br}$ , its reaction with  $\text{MeMgBr}$  replaces the bromide by a methyl group suggesting attack at the metal rather than at the allyl ligand as had been expected. Similarly, reaction with  $\text{LiBHEt}_3$  forms  $\text{Tp}'\text{Rh}(\eta^3\text{-C}_3\text{H}_5)(\text{H})$ , but when  $\text{LiBDEt}_3$  is used, incorporation of deuterium into the allyl ligand occurs to give  $\text{Tp}'\text{Rh}(\eta^3\text{-CH}_2\text{CDCH}_2)(\text{H})$  in 92% isotopic purity. Also, reaction of  $\text{Tp}'\text{Rh}(\eta^3\text{-CH}_2\text{CDCH}_2)\text{Br}$  with  $\text{LiBHEt}_3$  forms  $\text{Tp}'\text{Rh}(\eta^3\text{-C}_3\text{H}_5)(\text{D})$  in 85% isotopic purity indicating that at least in this system, initial attack of hydride (or deuteride) occurs at the allyl ligand to form (169), which then undergoes  $\beta$ -hydride (or deuteride) elimination.<sup>120</sup> Multiple insertions of mono(aryl)allenes into the initially formed allyl complex occurs when an excess of the allene is reacted with  $\text{Rh}(\text{H})(\text{PPh}_3)_4$  and (170) ( $\text{Ar} = p\text{-XC}_6\text{H}_4$  ( $\text{X} = \text{H}, \text{Me}, \text{OMe}, \text{Bu}^t, \text{Cl}, \text{F}$ );  $\text{L} = \text{PPh}_3$ ) is the product but with  $\text{Rh}(\text{H})(\text{CO})(\text{PPh}_3)_3$ , only the initial allyl complex (171) results.<sup>121</sup> The majority of the phosphine-complexed rhodium in the solution resulting from the addition of DPPB to  $[\text{Rh}(\mu\text{-H})(\text{COD})]_4$  is  $(\eta^3\text{-C}_8\text{H}_{13})\text{Rh}(\text{DPPB})$  resulting from partial hydrogenation of the COD ligand. Hydrogenolysis of this complex in the presence of DPPB forms  $\text{Rh}(\text{H})(\text{DPPB})_2$  via the postulated intermediate  $\text{Rh}(\text{H})(\text{DPPB})$ . This last species is considered to be the active catalytic species when a  $\text{DPPB}/[\text{Rh}(\mu\text{-H})(\text{COD})]_4$  mixture is used to catalyze the hydrogenation of carbon dioxide to formic acid (see *Organic Synthesis using Transition Metal Carbonyl Complexes*).<sup>122</sup>

Two equivalents of the potassium enolate  $\text{K}[\text{PhC}(\text{O})\text{CH}_2]$  react with  $[\text{Rh}(\mu\text{-Cl})\text{L}_2]_2$  to form the oxoallyl complex  $(\eta^3\text{-CH}_2\text{C}(\text{Ph})\text{O})\text{RhL}_2$  ( $\text{L} = \text{PPh}_3$ ), a rare example of a complex containing an unsupported oxoallyl ligand. Addition of an extra ligand causes an isomerization to the enolate complex  $\text{Rh}(\text{OC}(\text{Ph})=\text{CH}_2)(\text{L}')\text{L}_2$  ( $\text{L}' = \text{CO}, \text{Bu}^t\text{NC}$ ). The reactivity of the  $(\eta^3\text{-CH}_2\text{C}(\text{Bu}^t)\text{O})\text{RhL}_2$  analog differs markedly in that with CO the products are pinacolone and  $[\text{Rh}(\mu\text{-CO})(\text{CO})\text{L}_2]_2$ , while with the isocyanide the

oxoallyl ligand rearranges to the carbon-bound form in  $\text{Rh}(\text{CH}_2\text{C}(\text{O})\text{Bu}^t)\text{L}_2(\text{CNBu}^t)_2$ . The differences in reactivity as compared with analogous allyl complexes are attributed to the greater stability of the  $\eta^1$ -enolate form as compared with an  $\eta^1$ -allyl.<sup>123</sup> Following the standard procedure,  $(\eta^3\text{-allyl})\text{Rh}(\text{COD})$  (allyl =  $\text{C}_3\text{H}_5$ , 2-Me- $\text{C}_3\text{H}_4$ ) is generated from reaction of  $(\text{allyl})\text{MgBr}$  with  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  and the COD can be replaced by various bis(phosphino)methane ligands giving  $(\eta^3\text{-allyl})\text{Rh}(\text{R}_2\text{CH}_2\text{PPr}^i_2)$  ( $\text{R} = \text{Pr}^i, \text{cy}, \text{Ph}$ ). These initially add one carbonyl ligand to the metal but in the presence of excess CO undergo a reversible migratory insertion of CO into the allyl group to give the acyl complexes  $\text{Rh}(\text{C}(\text{O})\text{CH}_2\text{C}(\text{R}')=\text{CH}_2)(\text{CO})_2(\text{R}_2\text{CH}_2\text{PPr}^i_2)$  ( $\text{R}' = \text{H}, \text{Me}$ ).<sup>124</sup> An attempt to generate an acyl carbene complex from the reaction of  $[\text{Rh}(\mu\text{-Cl})(\text{PPr}^i_3)_2]_2$  and  $\text{PhC}(\text{O})\text{CHN}_2$  led instead to the acyl ylide complex (172)<sup>125</sup> while action of vinylmagnesium bromide on the vinylidene complex  $\text{trans-Rh}(\text{C}=\text{CHR})\text{Cl}(\text{PPr}^i_3)_2$  initially formed (46) ( $\text{R} = \text{H}, \text{Bu}^t, \text{Ph}$ ;  $\text{L} = \text{PPr}^i_3$ ), but on standing in benzene solution this underwent coupling of the vinyl and vinylidene ligands to yield (173) (see also Section 2.3). Similarly,  $\text{trans-Rh}(\text{C}=\text{CHR})(\text{Me})(\text{PPr}^i_3)_2$ , prepared in an analogous fashion at low temperature undergoes C–C coupling (see *Organic Synthesis Using Metal-mediated Coupling Reactions*) at room temperature to form  $(\eta^3\text{-1-R-C}_3\text{H}_4)\text{Rh}(\text{PPr}^i_3)_2$  ( $\text{R} = \text{H}, \text{Ph}, \text{Bu}^t$ ). For  $\text{R} = \text{H}, \text{Ph}$  the syn isomer forms, while  $\text{R} = \text{Bu}^t$  gives the anti.<sup>126</sup>

A series of DFT calculations (see *Molecular Orbital Theory*) on  $\text{Rh}(\eta^3\text{-C}_3\text{H}_5)_3$  indicate that the ground-state structure has no symmetry. Calculated ionization energies agree well with values obtained from photoelectron spectra. The calculated potential-energy surface indicates the presence of three transition states, one of which involves an  $\eta^1$ -allyl ligand between the several minima that are found, and variable-temperature NMR measurements appear consistent with there being three distinct fluxional processes (see *Stability Constants & their Determination*).<sup>127</sup>

## 4.2 Arene Complexes

Arene complexes figure prominently in a series of investigations into the synthesis of metallamacrocyclic complexes. The first report is on **(174)** ( $X = \text{CH}_2$ ;  $Y = \text{H, F}$ ;  $X = \text{O}$ ;  $Y = \text{H}$ ) that are obtained from  $\text{Ph}_2\text{PCH}_2\text{CH}_2\text{XC}_6\text{H}_4\text{Y}$  and  $[\text{Rh}(\text{COE})(\text{THF})_2]\text{BF}_4$ , while an analogous route with 1,4- $(\text{Ph}_2\text{PCH}_2\text{CH}_2\text{O})_2\text{C}_6\text{R}_4$  ( $\text{R} = \text{Me}$ ) forms the dinuclear species **(175)**. Using the more flexible ligand 1,4- $(\text{Ph}_2\text{PCH}_2\text{CH}_2\text{CH}_2\text{O})_2\text{C}_6\text{R}_4$  ( $\text{R} = \text{Me}$ ) allows for arene coordination and **(176)** is formed instead. Interestingly, with the ligand 4,4'- $(\text{Ph}_2\text{PCH}_2\text{CH}_2)_2\text{C}_6\text{H}_4\text{C}_6\text{H}_4$  arene coordination also occurs and **(177)** is formed. The coordination of the oxygen atoms in **(175)** and the arene groups in **(176)** and **(177)** serve to initially satisfy the coordination requirements of the metal and constitute a “weak link” approach to directing the synthesis in an efficient manner toward the final metallamacrocycle. Thus, successive reaction of **(176)** with acetonitrile and then carbon monoxide displaces the arene from the metal and forms **(178)** ( $\text{R} = \text{Me}$ ). Similarly, the “weak links” in **(175)** and **(177)** are disrupted by carbon monoxide to form **(179)** ( $n = 1$ ;  $\text{R} = \text{Me}$ .  $n = 2$ ;  $\text{R} = \text{H}$ ), while reaction of **(175)** with 1,4-diisocyanobenzene in acetonitrile forms the “occupied” metallamacrocycle **(180)**.<sup>128</sup> The calix-shaped metallacyclophane **(181)** is formed from 9,10-bis(2-diphenylphosphinoethyl)anthracene and  $[\text{Rh}(\mu\text{-Cl})(\text{CO})_2]_2$  at a low temperature.<sup>129</sup>

Complexes of formula  $[(\eta^6\text{-arene})\text{Rh}(\text{CO})\text{L}]\text{PF}_6$  (arene =  $\text{C}_6\text{H}_6$ ,  $\text{C}_6\text{H}_5\text{CF}_3$ ,  $\text{C}_6\text{H}_5\text{OMe}$ , mesitylene, 1,3,5- $(\text{MeO})_3\text{C}_6\text{H}_3$ ;  $\text{L} = \text{PPR}^i_3$ ) are readily formed by displacement of the weakly bound solvent from  $[\text{Rh}(\text{COE})(\text{L})(\text{acetone})_2]\text{PF}_6$  by the arene, and the COE ligand can be then replaced by the more strongly bonding alkene ethylene. Treatment

of  $[\text{Rh}(\text{COE})(\text{PPR}^i_3)(\text{acetone})_2]\text{PF}_6$  with  $\text{Pr}^i_2\text{P}(\text{CH}_2)_n\text{Ph}$  ( $n = 2, 3$ ) forms **(182)** ( $\text{L} = \text{COE}$ ) and analogs with  $\text{L} = \text{C}_2\text{H}_4$ , maleic anhydride,  $\text{EtO}_2\text{CC}\equiv\text{CH}$ ,  $\text{SbPr}^i_3$ , and  $\text{Pr}^i_2\text{P}(\text{CH}_2)_n\text{Ph}$  can be prepared by substitution reactions.<sup>130</sup>

Photolysis (see **Photochemistry of Transition Metal Complexes**) of a mixture of  $\text{CpRh}(\text{C}_2\text{H}_4)_2$  and hexamethylbenzene in hexane solution forms a mixture of **(183)** and **(184)**. Analogs are similarly formed with biphenyl under the same conditions.<sup>131</sup> The tetrameric borole complex  $[\text{Rh}(\mu_3\text{-I})(\eta^5\text{-C}_4\text{H}_4\text{BPh})_4]$  is converted to  $[(\eta^5\text{-C}_4\text{H}_4\text{BPh})\text{Rh}(\text{MeCN})_3]\text{BF}_4$  by halide abstraction with  $\text{AgBF}_4$ . The acetonitrile can be

replaced by hexamethylbenzene to give  $[(\eta^5\text{-C}_6\text{H}_6\text{BPh})(\eta^6\text{-C}_6\text{Me}_6)\text{Rh}](\text{BF}_4)$ , but if the acetonitrile complex is taken to dryness it polymerizes to (185).<sup>132</sup> A final report on arene complexes concerns the chemistry of rhodium complexes containing  $\eta^6$ -coordinated tetraphenylborate ions (see **Boron: Organoboranes**). For example,  $(\text{C}_2\text{H}_4)_2\text{Rh}(\eta^6\text{-C}_6\text{H}_5\text{BPh}_3)$  plus  $n - 1$  equivalents of  $(\text{C}_2\text{H}_4)_2\text{Rh}(\text{OTf})$  forms  $\{[(\text{C}_2\text{H}_4)_2\text{Rh}(\eta^6\text{-C}_6\text{H}_5)]_n\text{BPh}_{4-n}\}(\text{OTf})_{n-1}$  ( $n = 2, 3$ ). The complexes in THF or dichloromethane solution under dinitrogen decompose to form biphenyl, benzene, ethylbenzene, and styrene. The formation of the last two products indicates a process transferring a phenyl group to an ethylene ligand and the formation of a species such as  $\{(\text{C}_2\text{H}_4)_2\text{Rh}(\text{C}_6\text{H}_5)\}$  is proposed.<sup>133</sup>

## 5 MISCELLANEOUS COMPLEXES

A new report on oxapentadienyl complexes includes the reaction of  $[\text{Rh}(\mu\text{-Cl})\text{L}_2]_2$  with several potassium oxapentadienides to form a mixture of the isomers (186) and (187) ( $\text{L} = \text{PMe}_3, \text{PEt}_3$ ;  $\text{R} = \text{Me}, \text{H}$ ). When  $\text{L} = \text{PEt}_3$  and  $\text{R} = \text{Me}$ , reaction of (186) with methyl triflate forms (188), while with  $\text{HBF}_4$  a mixture of (189) and (190) is obtained.<sup>134</sup> Reaction of diphenyl ketene with  $[\text{Rh}(\mu\text{-Cl})(\text{COE})_2]_2$  and four equivalents of a phosphine forms *trans*- $\text{RhCl}(\eta^2\text{-O}=\text{C}=\text{CPh}_2)\text{L}_2$  ( $\text{L} = \text{PPr}^i_3, \text{Pcy}_3, \text{PBu}^i_2\text{Me}$ ) where it is the  $\text{C}=\text{O}$  bond which is coordinated with the metal. In comparison to the iridium analog, there is less  $\pi$ -backbonding. The isotopically labeled complexes with  $\text{Ph}_2\text{C}=\text{C}^{13}\text{O}$  and  $\text{Ph}_2\text{C}=\text{C}=\text{C}^{18}\text{O}$  were also prepared and used to analyze the infrared spectrum leading to an identification of the  $\text{C}=\text{O}$  stretching vibration of the coordinated ketene.<sup>135</sup> Condensation of  $[\text{Cp}^{\text{u}}_2\text{ZrS}_2]^{2-}$  ( $\text{Cp}^{\text{u}} = 1,3\text{-Bu}^i_2\text{C}_5\text{H}_3$ ) with  $[\text{Rh}(\mu\text{-Cl})(\text{L}_2)]_2$  forms (191) ( $\text{L}_2 = \text{COD}, \text{NBD}, \text{TFB}$ ). The same complex can also be synthesized from  $\text{Cp}^{\text{u}}_2\text{Zr}(\text{SH})_2$  and  $\text{Rh}(\text{acac})(\text{L}_2)$ . Replacement of the diolefin ligands in (191) with carbon monoxide occurs readily and one carbonyl ligand on each rhodium can then be replaced by a phosphine or a phosphite.<sup>136</sup> Hydrolysis of  $\text{Cp}^*\text{TaMe}_4$  with two equivalents of  $[\text{Rh}(\mu\text{-OH})(\text{COD})]_2$  forms (192) and this is further hydrolyzed by 4,6-dimethyl-2-hydroxy-3-cyanopyridine to yield (193).<sup>137</sup>

The uncoordinated phosphorus atoms in  $[\text{Pt}_2(\mu\text{-dpmp})_2\text{L}_2](\text{PF}_6)_2$  ( $\text{L} = \text{xylylisocyanide}$ ) can bind a rhodium atom in

the reaction with  $[\text{Rh}(\mu\text{-Cl})(\text{COD})]_2$  to form a mixture of (194) and (195). Reaction of (195) with carbon monoxide forms (196) while with methyl propiolate (197) ( $\text{R} = \text{Me}$ ) is the product.<sup>138</sup>

DFT calculations (*see Molecular Orbital Theory*) on  $\text{CpRh}(\text{CO})_2$  and  $[\text{RhCl}_2(\text{CO})_2]^-$  have been used to determine the ground-state molecular structures, and these structures with symmetry-adapted cluster-configuration interaction calculations have been used to explore the nature of excited states (*see Electronic Structure of Organometallic Compounds*). The ground state is predicted to be a singlet with the triplet state lying significantly above it. The activation process for the anion is predicted to be thermal dissociation of a carbonyl ligand but this process requires much more energy in the neutral complex. In the excited state of the anion, all strong absorptions are  $\text{Rh} \rightarrow \text{CO}$  MLCT in nature while for  $\text{CpRh}(\text{CO})_2$  the  $\text{Rh} \rightarrow \text{CO}$  MLCT and the  $\text{Cp} \rightarrow \{\text{Rh} + \text{CO}\}$  absorptions are strongly mixed in the higher excited states with the latter having the greater oscillator strength. The results suggest that the low quantum efficiency for  $\text{CpRh}(\text{CO})_2$  to activate C-H and Si-H bonds can be attributed to a low proportion of MLCT excitation in the higher excited states (*see Photochemistry of Transition Metal Complexes and Luminescence Behavior & Photochemistry of Organotransition Metal Compounds*).<sup>139</sup> Enthalpies of addition of CO,  $\text{H}_2$ , and  $\text{Bu}^t\text{NC}$  to  $[\text{Rh}(\mu\text{-Cl})(\text{PPr}_3)_2]_2$  (which has been conclusively determined to be dimeric in solution) have been measured<sup>140</sup> (*see Bonding Energetics of Organometallic Compounds*) and the analog  $[\text{Rh}(\mu\text{-Cl})(\text{Bu}^t_2\text{PCH}_2\text{PBU}^t_2)]_2$  has been prepared. In solution, this latter species is thought to convert to the solvated monomer  $\text{RhCl}(\text{Bu}^t_2\text{PCH}_2\text{PBU}^t_2)(\text{S})$  and is a catalyst precursor for the hydrosilylation of but-2-yne by  $\text{HSi}(\text{OEt})_3$  (*see Hydrosilylation Catalysis*). A much better system uses  $\text{Rh}(\text{Me})(\text{Bu}^t_2\text{PCH}_2\text{PBU}^t_2)(\text{PMe}_3)$  which is prepared by addition of  $\text{PMe}_3$  to  $\text{RhCl}(\text{Bu}^t_2\text{PCH}_2\text{PBU}^t_2)(\text{S})$  followed by reaction with methyl lithium. This system shows a high selectivity for the cis hydrosilylation product and the resting state of the catalyst is thought to be  $\text{Rh}(\text{PMe}_3)(\text{Si}(\text{OEt})_3)(\text{Bu}^t_2\text{PCH}_2\text{PBU}^t_2)$ , which could be isolated from reaction of  $\text{Rh}(\text{Me})(\text{Bu}^t_2\text{PCH}_2\text{PBU}^t_2)(\text{PMe}_3)$  and the silane at low temperature.<sup>141</sup>

## 1 INTRODUCTION

Ruthenium was first recognized as a distinct metal in 1844 in Estonia by Clauss and was named after Ruthenia (Russia).

However, its blue chloride solution had been previously observed by Vauquelin in Paris in 1804. Ruthenium is the least abundant platinum metal ( $10^{-3}$  to  $10^{-4}$  ppm) after rhodium. In 2002, the demand for ruthenium was 11.6 tons, an increase of 1.8 tons compared to 2001, mainly because of increased sales of ruthenium paste to the electronics industry, for the manufacture of chip resistors and hybrid integrated circuits (HIC). Its atomic number is 44, its atomic weight 101.07, and its electronic configuration  $[\text{Kr}]4d^7 5s^1$ . Seven stable isotopes are known. Some physical data are reported in Table 1 (see **Coordination Chemistry: History and Coordination Numbers & Geometries**).

Among the platinum metals, ruthenium shows the largest range of oxidation states, from  $-II$  to  $+VIII$ , with most of the inorganic chemistry taking place in the  $+II$  and  $+III$  states. The chemistry of ruthenium has been comprehensively reviewed in a monograph in 1984 and in '*Comprehensive Coordination Chemistry*' in 1987 and 2003.<sup>1–4</sup> In the most recent review, the results (including osmium chemistry) have been divided into two chapters referring to low- and high-oxidation states.<sup>3,4</sup>

This article represents an updated version of the one published in EIC-1. It is organized in the same way, with a survey of the coordination and inorganic chemistry of ruthenium, classified by the nature of the ligand, together with recent highlights in this field. Some old references will not be quoted and can be found in EIC-1. It is worth noting that the border with organometallic chemistry remains tenuous (see, for example, the use of classical coordination compounds for catalyzing organic reactions; see **Ruthenium: Organometallic Chemistry**).

## 2 RUTHENIUM–HALIDE COMPLEXES

Compounds of the formulation  $\text{RuX}_3$  are known for all four halides ( $X = \text{F}, \text{Cl}, \text{Br}, \text{I}$ ).  $\text{RuCl}_3$  exists as two well-characterized phases ( $\alpha\text{-RuCl}_3$  and  $\beta\text{-RuCl}_3$ ), which

**Table 1** Selected physical properties of ruthenium

Scheme 1

are prepared by heating ruthenium metal in a stream of CO/Cl<sub>2</sub> at 600 to 700 °C and 330 to 340 °C, respectively. In contrast, the complex commonly known as 'hydrated ruthenium trichloride', or 'RuCl<sub>3</sub>·xH<sub>2</sub>O', is readily soluble in various polar solvents and is commercially available. It is by far the most common starting material in ruthenium chemistry, whether inorganic or organometallic (see Scheme 1 for selected examples of important compounds). However, it was demonstrated that this species actually corresponds to a mixture of different ruthenium compounds, mostly in the +IV oxidation state. Species such as H<sub>3</sub>[Cl<sub>3</sub>Ru(μ-OH)<sub>3</sub>RuCl<sub>3</sub>] and H<sub>3</sub>[Cl<sub>3</sub>Ru(μ-OH)<sub>2</sub>(μ-O)RuCl<sub>3</sub>] have been shown to exist in

the mixture. We will, nevertheless, refer to the common commercial name throughout this article.

A large number of mixed-ligand ruthenium(III) halides are known. One of the simplest is K<sub>2</sub>[RuCl<sub>5</sub>(H<sub>2</sub>O)], which is a valuable well-defined Ru<sup>III</sup> starting material. A series of dinuclear complexes Ru<sub>2</sub>Cl<sub>4</sub>(dppb)<sub>2</sub>L can be obtained by electrolysis from the corresponding RuCl<sub>3</sub>(dppb)L complexes.<sup>5</sup> There is no strong evidence for the existence of any RuX<sub>2</sub> complexes. However, reduction of RuCl<sub>3</sub>·3H<sub>2</sub>O by various reagents (Zn, H<sub>2</sub>/PtO<sub>2</sub>, Na/Hg, Zn/Hg, etc.) in alcoholic or aqueous solutions affords a deep-blue solution (first observed by Vauquelin). The nature of such solutions is still controversial. Investigations by Rose and Wilkinson in the late 1960s have concluded in favor of the presence of the anionic cluster [Ru<sub>5</sub>Cl<sub>12</sub>]<sup>−</sup>, although no X-ray evidence is as yet available on this compound. It was, nevertheless, found to be a valuable precursor for the synthesis of a large variety of ruthenium (II) derivatives. Bino and Cotton have shown that addition of tetraethylammonium chloride to the deep-blue solution obtained upon dissolving Ru<sub>2</sub>(OAc)<sub>2</sub>Cl in 12 M HCl led to a green crystalline material, shown to be the homoleptic trimer [Ru<sub>3</sub>Cl<sub>12</sub>]<sup>6−</sup> containing Ru(III), Ru(II), and Ru(III) with short Ru–Ru distances (2.805(1) Å) in agreement with single Ru–Ru bonds.

Some homoleptic fluorides of ruthenium are well characterized up to the oxidation state +VI: RuF<sub>6</sub> is a volatile dark-brown solid. Mixed-ligand complexes such as RuOF<sub>4</sub> are also known. RuF<sub>4</sub> has been isolated by treatment of AsF<sub>5</sub> with [RuF<sub>6</sub>]<sup>2−</sup> in a HF solution.<sup>6</sup> With the other halides, the chemistry starts at the oxidation state IV. RuCl<sub>4</sub> can be observed in the gas phase between 400 and 800 °C, whereas the dianions MX<sub>6</sub><sup>2−</sup> (X = F, Cl, Br) are stable. During the last decade, considerable progress has been made in the field of transition metal–fluoride complexes. Several fluoride(carbonyl) complexes have been characterized (see **Carbonyl Complexes of the Transition Metals**). A series of bifluoride HF<sub>2</sub> complexes incorporating mono- or diphosphines are now available.<sup>7</sup> In particular, two bifluoride complexes can be isolated from *cis*-RuH<sub>2</sub>(dmpe)<sub>2</sub>. The hydride complex *trans*-RuH(HF<sub>2</sub>)(dmpe)<sub>2</sub> (**1**) was obtained by addition of Et<sub>3</sub>N·3HF or by reaction with fluoroarenes as a result of C–F activation, whereas reaction with fluoroalkenes produced the fluoride complex *cis*-RuF(HF<sub>2</sub>)(dmpe)<sub>2</sub> (**2**). The coordination mode of

the fluoro ligand, terminal versus bridging, plays an important role in the stabilization of  $d^6$  and  $d^8$  complexes.<sup>8</sup>

### 3 RUTHENIUM COMPLEXES OF OXYGEN-DONOR LIGANDS (See *Water & O-donor Ligands*)

#### 3.1 Ruthenium Homoleptic Oxo Species

The ruthenium(VIII) complex  $\text{RuO}_4$  and salts such as  $\text{K}_n[\text{RuO}_4]$ , derived by reduction ( $n = 1-3$ ), have been reported in the literature. However, the compound originally thought to be the ruthenium(VI) oxide  $[\text{RuO}_4]^{2-}$  has been identified by X-ray crystallography as  $[\text{RuO}_3(\text{OH})_2]^{2-}$ .  $\text{RuO}_4$  is a yellow, crystalline, low-melting ( $25.4^\circ\text{C}$ ), and highly volatile solid. Care must be taken when using it since it is a highly toxic and powerful oxidizing agent. It reacts explosively with a variety of organic solvents. It is, nevertheless, a useful oxidizing reagent for organic substrates such as alcohol, amine, sulfide, and so on. The perruthenate ( $n\text{Pr}_4\text{N}$ ) $\text{RuO}_4$  salt is a useful, mild, and selective oxidant of alcohols to aldehydes or ketones, even in allylic systems.  $\text{O}_2$  or NMO is used as co-oxidant.<sup>9</sup> Interestingly, the salt can be recovered when using ionic liquids (see *Oxidation Catalysis by Transition Metal Complexes*).<sup>10</sup> The ruthenium(IV) oxide,  $\text{RuO}_2$ , is a stable metallic oxide displaying a low chemical reactivity but interesting physical properties. Under high pressure, the rutile form of  $\text{RuO}_2$  can be converted to a new cubic phase, which presents a very low compressibility (comparable to that of diamond).<sup>11</sup>

#### 3.2 Mixed-ligand Oxo Derivatives

The study of mixed-ligand oxo derivatives is closely related to the use of these species in catalytic oxidation systems (including the epoxidation of alkenes and the oxidation of alkanes. See *Oxidation Catalysis by Transition Metal Complexes*). In such complexes, the oxo group can be terminal, doubly bridging, or triply bridging.

The chemistry of triply bridging oxo(carboxylate) ruthenium clusters of general formula  $[\text{Ru}_3(\mu_3\text{-O})(\mu_2\text{-O}_2\text{CR})_6(\text{L})_3]^n$  (3) has been extensively developed. A rich chemistry is associated with the strong electronic and magnetic interactions involving Ru(II), Ru(III), and Ru(IV) centers. They are relevant to biomimetic systems, redox catalysis, and molecular devices.<sup>12</sup> A number of dinuclear ruthenium complexes incorporating a bridging oxygen have been isolated and used as a water oxidation catalyst. The  $\mu$ -oxo(bipyridyl) dimer  $[\{\text{Ru}(\text{bpy})_2(\text{OH}_2)\}_2\text{O}]^{4+}$  (known as 'blue ruthenium dimer') is one of the most effective electrocatalytic reagents. The mechanism by which it oxidizes water to dioxygen is very complex (loss of  $4e^-$  and  $4\text{H}^+$ ) and has been extensively investigated by Meyer *et al.*<sup>13</sup>

Monooxo and dioxo ruthenium (IV), (V), and (VI) complexes have been extensively studied. Che's group has been very active in this area, and a very detailed analysis of this field can be found in the chapter written by Che and Lau and published in '*Comprehensive Coordination Chemistry*'.<sup>4</sup> The chapter covers the various aspects of the chemistry (synthesis; characterization, including the Pourbaix diagrams for many representative species; reactivity; and catalysis). The most important classes of ligands for such  $\text{Ru}(\text{O})_n$  centers are (1) the porphyrins; (2) the macrocyclic tertiary amine ligands (see *Macrocyclic Ligands*); and (3) the pyridine, polypyridyl, and related ligands. Most of the compounds are very active oxidants for a variety of organic and inorganic substrates.

Groves *et al.* isolated the first dioxoruthenium(VI) porphyrin complex  $\text{Ru}(\text{O})_2\text{TMP}$ , able to efficiently catalyze the aerobic epoxidation of alkenes at ambient temperature and pressure.<sup>14</sup> A number of dioxo  $[\text{Ru}(\text{O})_2(\text{por})]$  and oxo(imido)  $[\text{Ru}(\text{O})(\text{por})(\text{NR})]$  complexes of Ru (VI) with porphyrinato (por) ligands are now available. All these Ru(VI) complexes are diamagnetic. Complexes incorporating chiral porphyrins have also been isolated, and for example, enantioselective aerobic epoxidation of alkenes is achieved by complex (4). Recent developments involve the design of dendritic ruthenium porphyrins.<sup>15</sup> Similar high-oxidation oxo complexes can be prepared using various macrocyclic amine ligands such as [14]ane-N4 (5) or 14-tetramethylcyclam (TMC) and their 15- and 16-member analogs. A cis configuration, as in complex (6), can be obtained using a triazacyclononane ligand. (6) oxidizes disubstituted alkynes to 1,2 diketones in good yields.<sup>16</sup>

Bis-oxo-Ru(VI) complexes containing nonlabile oxidation-resistant nitrogen-donor ligands such as pyridine, bipyridine,

(4)

terpyridine, and related ligands are another important class of compounds that behave as four-electron oxidants and convert alcohols to aldehydes or ketones. The remarkable reactivity of high-oxidation-state ruthenium and osmium polypyridyl complexes has been recently reviewed by Meyer and Huynh.<sup>17</sup> The polypyridyl species are stronger oxidants than the macrocyclic family. The chemistry of periodato-derived species has been developed, and for example, the complex,  $[\text{Ru}(\text{O})_2(\text{bpy})\{\text{IO}_3(\text{OH})_3\}]$  (**7**), containing the triply protonated periodate ligand  $[\text{I}(\text{O})_3(\text{OH})_3]^{2-}$  has been isolated. (**7**) behaves as a six-electron oxidant for the stoichiometric oxidation of alkenes.<sup>18</sup> Chloro and carboxylato dioxo complexes of Ru(VI) have been prepared and are also used as oxidants of halides, alcohols, sulfides, and even alkanes (see *Oxidation Catalysis by Transition Metal Complexes*).

(7)

### 3.3 Carboxylate Ligands

The carboxylate group can act as a three-electron bridging or chelating ligand, as well as a one-electron monodentate ligand. This gives rise to a rich chemistry in which interconversion between the modes of coordination of the ligand and nuclearity of the complexes is facile. Examples of chelation are found in the phosphine adducts  $\text{Ru}(\text{OAc})_2(\text{PPh}_3)_2$  and  $\text{RuH}(\text{OAc})(\text{PPh}_3)_3$ , which are prepared by metathetical exchange with chloride groups or by protonation of polyhydrides with acetic acid. The dicarboxylate complexes  $\text{Ru}(\text{OAc})_2(\text{BINAP})$  are at the origin of all the chemistry developed by Noyori in asymmetric catalytic hydrogenation reactions (see Section 6.2). Similar complexes of the formula

$\text{Ru}(\text{O}_2\text{CCF}_3)_2(\text{ROH})_2(\text{PP})$ , incorporating various chiral phosphines (PP (diphosphines)), have also been characterized. The two carboxylates act as monodentate ligands, and two solvent molecules remain in the coordination sphere of the metal, in *cis* positions.<sup>19</sup>

Bridging carboxylates are mainly found in three types of structures:  $\mu_3$ -oxo-bridged trimers,  $\mu_2$ -oxo- or hydroxo-bridged dimers (see Section 3.2), and metal–metal multiply bonded dimers. Diruthenium tetracarboxylates exist as homovalent  $\text{Ru}_2(\text{II},\text{II})$  and mixed-valent  $\text{Ru}_2(\text{II},\text{III})$  species (see *Mixed Valence Compounds*). They all adopt the familiar ‘lantern’ type motif (see structure (**8**)). The first dimers  $[\text{Ru}_2(\text{OCOR})_4\text{Cl}]$  were prepared by reaction of  $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$  with a mixture of carboxylic acid/anhydride acid. The crystal structure of  $[\text{Ru}_2(\text{OCOMe})_4\text{Cl}]$  revealed the presence of infinite chains of  $\text{Ru}_2$  units linked by Cl. Analogous complexes can be prepared using a variety of acids. Diadducts of the type  $[\text{Ru}_2(\text{OCOR})_4\text{L}_2]\text{X}$  incorporate L ligands such as  $\text{H}_2\text{O}$ ,  $\text{OPPh}_3$ , THF, py, MeOH, and DMSO. The diruthenium carboxylate complexes display interesting magnetic and electronic properties as potential molecular materials and liquid crystals. They are now being tested as antitumor drugs.<sup>20</sup>

(8)

### 3.4 Other Oxygen-donor Ligands

Water reacts as a ligand in numerous inorganic and organometallic compounds. It normally behaves as a two-electron ligand on one ruthenium center, although some rare cases of water bridging two ruthenium centers are known. The homoleptic ruthenium(III) and ruthenium(II) complexes  $[\text{Ru}(\text{H}_2\text{O})_6]^{n+}$  have been known for nearly 40 years. In the course of their studies on Ring Opening Metathesis Polymerization (ROMP) reactions, Grubbs *et al.* explored the reactivity of  $[\text{Ru}(\text{H}_2\text{O})_6](\text{tosyl})_2$  with acyclic- and monocyclic-functionalized alkenes (L), generating monoalkene adducts  $[\text{Ru}(\text{H}_2\text{O})_5\text{L}]^{2+}$  (see *Water & O-donor Ligands*).<sup>21</sup>

Hydroxy ligands generally result from the protonation of oxo or deprotonation of aqua species and are thus found in systems similar to those described above. They occupy terminal or doubly or triply bridging positions. Alternative routes involve the metathetical exchange of  $\text{Cl}^-$  by  $\text{OH}^-$  or oxidative addition of  $\text{H}_2\text{O}$ . These routes have been used by Wilkinson *et al.* to prepare unsaturated trans hydroxo

hydrido derivatives such as  $\text{RuH}(\text{OH})(\text{PPh}_3)_2(\text{H}_2\text{O})$ .<sup>1,2</sup> A series of alkoxide and hydroxide complexes have now been designed by Bergman *et al.*, and their properties and reactivities have been reviewed. The complexes, with a strongly polarized Ru–O bond, typically display nucleophilic reactivity (see *Water & O-donor Ligands*).<sup>22</sup> The formation of an (alkoxy)ruthenium hydride and a piperidinyloxy species are postulated in the  $\text{RuCl}_2(\text{PPh}_3)_3/\text{TEMPO}$ -catalyzed aerobic oxidation of alcohols.<sup>23</sup>

$\text{Ru}(\text{acac})_3$  is readily prepared from  $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$ , 2,4-pentanedione, and potassium hydrogencarbonate in hot water. Its structure has been determined by X-ray and neutron diffraction measurements at various temperatures.<sup>24</sup> This compound can be reduced to  $[\text{Ru}(\text{acac})_3]^-$ . Protonation leads to liberation of  $\text{acacH}$ , thus making this compound a suitable starting material for ruthenium(III) chemistry.  $\text{Ru}(\text{acac})_3$ -mediated oxidative di- and trimerization of 1,3-diamino benzene produce new diimine  $\text{Ru}(\text{acac})_2$  complexes.<sup>25</sup> Ruthenium complexes with the bulky  $\text{N}(\text{SPR}_2)_2$  ligand, a sulfur analogue of  $\text{acac}$ , have been synthesized.<sup>26</sup>

#### 4 RUTHENIUM COMPLEXES OF SULFUR-DONOR LIGANDS (See *S-donor Ligands*)

Ruthenium–sulfur systems have attracted attention, primarily owing to their relevance to biology and catalysis, in particular, for the hydrodesulfurization process. (see *Hydrodesulfurization & Hydrodenitrogenation*). Soft sulfur ligands alone cannot stabilize Ru(VI) centers, and no Ru(V) complexes seem to have been reported with any sulfur ligands. Sulfide, thiolate, and thioether ligands are unique as they display versatile electronic properties: they can act as pure  $\sigma$ -donors,  $\sigma$ -donor  $\pi$ -acceptors, or even as  $\sigma$ - $\pi$ -donors because of their lone pairs (see *Subvalent Compounds*). The coordination chemistry of new mixed-donor ligands is now being investigated to benefit from the properties of the different atoms N, P, O, and S (see *Sulfur: Inorganic Chemistry*).

##### 4.1 Sulfides and Thiolato Ligands

Ruthenium sulfide ( $\text{RuS}_2$ ) as well as other chalcogenides  $\text{RuX}_2$  ( $\text{X} = \text{Se}, \text{Te}$ ) adopt a cubic pyrite structure and should be regarded as  $\text{Ru}^{2+}(\text{S}_2)^{2-}$ . They are very stable compounds that are readily prepared by several routes, including direct combination of the elements. The chemistry of ruthenium complexes with bridging sulfide groups has been particularly examined by Matsumoto *et al.* The synthesis and properties of a family of complexes with a strong  $\mu$ -donor ligand  $(\text{S}_2)^{2-}$  bridging two Ru centers have been described. Of particular interest is the reaction of (9) with  $\text{O}_2$ . Amongst other products, oxidation of the sulfide ligand results in the formation of (10) with a unique bridging  $\text{S}_2\text{O}_5^{2-}$  ligand.<sup>27</sup>

Numerous examples of complexes containing terminal or bridging thiolato ligands are known. For example, fluorinated thiolates Ru(II) and (III) species have been prepared in which  $\text{C}_6\text{F}_5\text{S}^-$  acts either as a terminal ligand or as a bridging ligand between two ruthenium centers.<sup>28</sup> Trigonal-bipyramidal Ru(IV) thiolate complexes display a characteristic trigonal-planar  $\text{Ru}(\text{SR})_3$  core, and the organometallic reactivity of these species is now being explored.<sup>29</sup> The homoleptic complex  $[\text{Ru}(\text{mnt})_3]^{2-}$  (11) with only sulfur atoms in the coordination sphere of ruthenium has been isolated. (11) decomposes in the presence of light, leading to the formation of a compound  $[\text{Ru}(\text{mnts})_2]^{2-}$  containing a novel tridentate (mnts) ligand.<sup>30</sup> Various examples of hydrido(thiolate) complexes have been reported. Interestingly, protonation can occur at the metal, or at the hydride to form a dihydrogen complex, or at the sulfur site to give a thiol complex (see Section 8). The reactivity of the bis(dihydrogen) complex  $\text{RuH}_2(\text{H}_2)_2(\text{PCy}_3)_2$  with sulfur heteroaromatic compounds leads to new compounds presenting different coordination modes of the S-substrates. As an example, C–S splitting in 2-acetylthiophene results in the formation of a dihydride metallocycle (12) with a new thiolato ligand  $\eta^2-(\text{O},\text{S})$  coordinated to ruthenium.<sup>31</sup>

##### 4.2 Thioethers and Analogous Derivatives

Numerous examples of complexes containing thioethers have been reported, including the first example by Sellmann *et al.* of a transition metal compound containing  $\text{H}_2\text{S}$ , namely,  $\text{Ru}(\text{SH}_2)(\text{PPh}_3)(\text{S}_4)$  ( $\text{S}_4 = 2,2'-(\text{ethylenedithio})\text{bis}(\text{thiophenolate})$ ). There is now an example of a room-temperature stable complex with a P–N ligand (see structure (13)).<sup>32</sup>

The remarkable complexing properties of cyclic thioethers, in particular, those exploited by Schröder's and Yoshida's groups, have stimulated a great interest in metal–thioether chemistry. These cyclic ligands bind preferentially to soft metal ions and have allowed the preparation of complexes displaying unusual stereochemistry and/or oxidation states. The most common thioethers involved are [9]ane- $\text{S}_3$ ,

[12]ane-S<sub>3</sub>, [12]ane-S<sub>4</sub>, [14]ane-S<sub>4</sub>, [16]ane-S<sub>4</sub>, and [18]ane-S<sub>6</sub>. The affinity of ruthenium for these thioethers (see structure (14)) is evidenced by the loss of arene upon reaction of [RuCl<sub>2</sub>(arene)]<sub>2</sub> with [9]ane-S<sub>3</sub>, yielding the homoleptic derivative [Ru([9]ane-S<sub>3</sub>)]<sup>2+</sup>. Neutral (such as [RuCl<sub>2</sub>(PR<sub>3</sub>)[9]ane-S<sub>3</sub>]), cationic ([RuCl(L<sup>1</sup>)(L<sup>2</sup>)([9]ane-S<sub>3</sub>)]<sup>+</sup>), or dicationic complexes ([Ru(L<sup>1</sup>)<sub>2</sub>(L<sup>2</sup>)([9]ane-S<sub>3</sub>)]<sup>2+</sup>) can be prepared as well as dinuclear species.<sup>33</sup>

(13)

(14)

Sellmann *et al.* have extensively surveyed the coordination properties of tetra- and pentadentate ligands in the search for reduction of N<sub>2</sub> by metal–sulfur complexes under mild conditions (see structures (15) and (16)).<sup>34</sup> The Ru‘S4’ core is not always preserved and partial cleavage of S–C bonds can occur. To circumvent this problem, the ethylene bridge in ‘S4’ has been replaced by an *o*-phenylene bridge.<sup>35</sup>

(15)

(16)

Pentaammine Ru(III) polarizes thiourea by complexing sulfur, and the complex [Ru(NH<sub>3</sub>)<sub>5</sub>SC(NH<sub>2</sub>)<sub>2</sub>](S<sub>2</sub>O<sub>6</sub>)<sub>3/2</sub>·H<sub>2</sub>O is isolated. The data are consistent with LMCT from a filled *pπ* sulfur orbital to the vacant *d<sub>xy</sub>π*-orbital on Ru(III).<sup>36</sup>

#### 4.3 Sulfoxides

Sulfoxide ruthenium complexes have received attention in part from the fact that they are useful starting materials for new organometallic and coordination compounds and in part from their role in biology and catalytic processes (see *Metal-related Diseases of Genetic Origin*). Potential applications are found in medicinal chemistry,

in particular as antitumor agents and as radiosensitizers. The complex Na{*trans*[RuCl<sub>4</sub>(DMSO)(Im)]} known as (NAMI), is the first ruthenium compound to enter clinical trials.<sup>37–39</sup>

RuCl<sub>2</sub>(DMSO)<sub>4</sub> can be conveniently prepared by refluxing RuCl<sub>3</sub>·3H<sub>2</sub>O in DMSO for a few minutes. This complex has found wide interest as a starting material, although DMSO is often difficult to eliminate. The sulfoxide ligand has two possible sites of coordination, sulfur and oxygen. Coordination to sulfur is generally observed in the case of ruthenium, and the *dπ*-S back-bonding plays a major role. S to O linkage isomerization was first shown, by Taube *et al.*, to occur upon oxidation of [Ru(NH<sub>3</sub>)<sub>5</sub>(DMSO)]<sup>2+</sup>. More recent studies demonstrate that DMSO can also be S-bonded to Ru(III) and Ru(IV) and suggest that the *κ*S-(DMSO) *σ*-donation to Ru is extensive in Ru(II) and Ru(IV) states.<sup>40</sup> The complex [Ru(bpy)<sub>2</sub>(DMSO)<sub>2</sub>]<sup>2+</sup> is yellow and has two S-bound DMSO ligands. Upon irradiation, a color change to red is observed, which is attributed to linkage isomerization from S- to O-bound DMSO. The yellow color is slowly recovered in the dark.<sup>41</sup>

#### 5 RUTHENIUM COMPLEXES OF NITROGEN-DONOR LIGANDS (See *Ammonia & N-donor Ligands*)

Supramolecular chemistry involving transition metal complexes has received increasing interest over the last decade. Photo-redox processes for solar energy conversion, information storage systems, biosensors, and complexes with antitumor activity are currently under investigation. In this area, the inorganic chemistry of ruthenium, largely dominated by the chemistry of nitrogen-donor ligands, plays a major role. Several important achievements in inorganic chemistry have involved nitrogen-donor ruthenium derivatives. These include (1) the first dinitrogen complexes, (2) the Creutz–Taube complex for the study of electron transfer and for the study of electron transfer in ruthenium-modified proteins, (3) the photochemistry of [Ru(bpy)<sub>3</sub>]<sup>2+</sup> and all the applications of this and related complexes (from photovoltaic cells to DNA intercalation), and (4) the aerobic oxidation of alkenes in the presence of ruthenium–porphyrin derivatives using both oxygen atoms.

The chemistry of the higher oxidation states is dominated by metal–ligand multiple bonds, with the oxo ligand being the ligand of choice. There are no complexes of Ru(VIII) and Ru(VII) incorporating an imido or a nitrido ligand and almost no Ru(V) compounds. A number of nitrido Ru(VI) complexes exist with a variety of ligands, but the chemistry is much less matured than the analogous osmium chemistry (see *Nitrides: Transition Metal Solid-state Chemistry*). There are no nitrido mononuclear Ru(IV) complexes, but a number of *μ*-nitrido species are known.

The simple amido complex  $[\text{Ru}(\text{NH}_3)_5(\text{NH}_2)]^{2+}$  can be easily prepared by deprotonation of  $[\text{Ru}(\text{NH}_3)_6]^{3+}$ , and a series of hydrido(amido) ruthenium complexes have been recently reported.<sup>22</sup> The chemistry of Ru(VI) imido complexes is largely concentrated on oxo(porphyrins) compounds of general formula  $\text{Ru}(\text{O})(\text{NR})(\text{por})$ . Extensive work on oxo ruthenium(VI) complexes incorporating N-ligands has been performed, as already mentioned in Section 3.2. Three main classes of ligands can be distinguished: (1) the porphyrins, (2) the macrocyclic tertiary amine ligands, and (3) the pyridine, polypyridyl, and related ligands. The results show a rich electrochemistry, and numerous studies are connected to the use of these compounds as oxidants for a variety of substrates (see *Oxidation Catalysis by Transition Metal Complexes*). Ruthenium porphyrins are efficient catalysts for a collection of organic reactions such as epoxidation and cyclopropanation of alkenes and hydroxylation and amidation of alkanes. For example, a dendritic ruthenium porphyrin efficiently catalyzes the EDA cyclopropanation of styrene.<sup>15</sup>

### 5.1 Ammine Salts

The hexammine ruthenium(II) salt  $[\text{Ru}(\text{NH}_3)_6]\text{Cl}_2$  is conveniently prepared by zinc reduction of  $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$  in aqueous ammonia. It is readily oxidized in several ways to the corresponding ruthenium(III) derivative,  $[\text{Ru}(\text{NH}_3)_6]^{3+}$ . The ruthenium(II) complex is substitutionally very labile, unlike the ruthenium(III) analogue, and complexes of the general formula  $[\text{Ru}(\text{NH}_3)_5(\text{L})]^{2+}$  display a very rich photochemistry.  $[\text{Ru}(\text{NH}_3)_5\text{N}_2]^{2+}$  was the first transition metal–dinitrogen complex, the discovery of which in 1965 stimulated the rapid development of nitrogen fixation chemistry (see *Nitrogenase Catalysis & Assembly*). The first compound containing a bridging dinitrogen group,  $[(\text{NH}_3)_5\text{Ru}(\text{N}_2)\text{Ru}(\text{NH}_3)_5]^{4+}$ , was then obtained by mixing  $[\text{Ru}(\text{NH}_3)_5\text{N}_2]^{2+}$  and  $[\text{Ru}(\text{NH}_3)_5(\text{H}_2\text{O})]^{2+}$ .<sup>1,2</sup> Studies on the photochemistry of Ru(II) ammine complexes really started in 1969 with molecular nitrogen complexes. The photochemical reactions are dominated by substitution processes. The studies provide a better knowledge into the excited states reactivity of  $d^6$  centers. The properties of the MLCT states in Ru(II)–ammine complexes depend on the nature of the L ligand. They can be varied by controlling the acidity of the medium and are solvent dependent. Several investigations have been focused on the prediction of electronic spectra and on identifying the extent of ruthenium–ligand electronic coupling in mononuclear and dinuclear species. The electronic spectra calculations are performed using modified INDO/s method (see *Photochemistry of Transition Metal Complexes; Photochemistry of Transition Metal Complexes: Theory*).<sup>42–44</sup>

Mixed-valence complexes exhibit interesting properties when significant electron coupling occurs between the donor and acceptor sites. Most of the systems are Ru(II)/Ru(III) species, but if electronic coupling is sufficient, there is a

complete blending of oxidation states and the odd electron is delocalized over both sites. The  $\mu$ -pyrazine-bridged dimer (17), also named the Creutz–Taube ion, was the first designed mixed-valence complex. The Nobel prize for chemistry was awarded to Taube in 1983 for his work on the mechanisms of electron transfer reactions (see *Electron Transfer in Coordination Compounds and Electron Transfer Reactions: Theory*).<sup>1–3</sup> The electronic structure of (17) has been the subject of numerous studies. The complex is considered ‘delocalized’ but appears to have properties of both class II and class III in the Robin and Day classification. In particular, its spectroscopic properties show some residual localization. It should now be considered as the prototype of a new class of mixed-valence species, Class II–III, as evidenced by Meyer *et al.*<sup>45</sup> Medium effects on charge transfer in metal complexes have also been reviewed by Meyer *et al.*<sup>46</sup> Inventing new analogues of the Creutz–Taube ion remains a very active area of research.<sup>47</sup>

(17)

Long-distance intervalence electron transfer is now demonstrated with metal–metal distances up to 25 Å. Distance dependence of electron transfer has strong implications for the search of, for example, molecular switch devices or biosensors. The bridging ligand dicyanamidobenzene has been extensively studied, and for example, complex (18) exhibits a very strong coupling (0.32 eV) for a metal–metal distance of 19.5 Å.<sup>48</sup>

### 5.2 $[\text{Ru}(\text{bpy})_3]^{2+}$ and Related Complexes. Some Selected Applications

A huge growth has been observed in  $[\text{Ru}(\text{bpy})_3]^{2+}$  chemistry over the last two decades as the complex displays a unique combination of air and thermal stability and redox and photophysical properties (see *Electron Transfer in Coordination Compounds and Electron Transfer Reactions: Theory*). More generally, ruthenium complexes incorporating pyridine or multidentate ligands based on aromatic imines have attracted more attention than all the other classes of inorganic ruthenium derivatives (see *Photochemistry of Transition Metal Complexes and Photochemistry of Transition Metal Complexes: Theory*).<sup>3</sup> An exhaustive database of bipyridine-containing molecules has now been reported.<sup>49</sup> Complexes of the general formula  $[\text{RuL}_6]^{2+}$  ( $\text{L} = \text{py}$ ;  $\text{L}_2 = \text{bpy}$ , phen, and derivatives;  $\text{L}_3 = \text{terpy}$ , etc.) can be prepared by a variety of

methods.<sup>1–3</sup> In the case of  $[\text{Ru}(\text{bpy})_3]^{2+}$ , a convenient method involves the reduction of  $\text{RuCl}_3$  with  $\text{H}_2$  over Pt black, followed by treatment with bpy in MeOH. The red crystals are obtained with 80% yield. It is out of the scope of this article to extensively review the photochemistry and photophysics studies on  $[\text{Ru}(\text{bpy})_3]^{2+}$  and related species, but we will give a few principles and highlight a few outstanding applications. Many investigations have benefited from the tremendous progress seen in various techniques (such as, for example, time-resolved femtosecond absorption spectroscopy).

$[\text{Ru}(\text{bpy})_3]^{2+}$  possesses a luminescent excited state,  $[\text{Ru}(\text{bpy})_3]^{2+*}$ , which can act as a reducing agent to give  $[\text{Ru}(\text{bpy})_3]^{3+}$  or as an oxidizing agent to give  $[\text{Ru}(\text{bpy})_3]^+$ . Therefore, the energy-transfer process may be coupled to either an oxidizing or a reducing agent. The redox potentials for couples involving  $[\text{Ru}(\text{bpy})_3]^{2+}$  and the excited state  $[\text{Ru}(\text{bpy})_3]^{2+*}$  are shown in Scheme 2. Its redox potentials are in favor of water splitting.

The design of new molecules, aimed at controlling the transfer of energy and of electrons from the excited state, is still an active area of research. The current understanding of electron flow through proteins has been achieved mainly through the use of photoprobes, with photoactive Ru(II)-diimine complexes being in widespread use.<sup>50</sup>

A rich chemistry has flourished in the search for new luminescent systems (see *Luminescence* and *Luminescence Behavior & Photochemistry of Organotransition Metal Compounds*). A great variety of inorganic architectures have been obtained, including helicates and large multicomponent arrays. As an example, rack-type polynuclear ruthenium

Scheme 2

complexes have been assembled by Lehn *et al.* These rack-type structures are based on tridentate ligands with pyrimidine and pyridine moieties. A fine tuning of the absorption and luminescence properties of these complexes can be performed by introducing substituents on the pyrimidine ring. These systems represent key structures for the development of photonic and electronic devices.<sup>51</sup> The control of the direction of the energy-transfer process in a multicomponent species offers new perspectives for artificial functions operating at the molecular level. The synthesis of multicomponent systems incorporating Ru(II) polypyridine and anthracene chromophores has been performed. The direction of the intercomponent energy-transfer process is reversed on passing from room temperature to 77 K.<sup>52</sup> Dendritic luminescent structures are now rather common as illustrated by the report in ‘*Inorganic Synthesis*’, of a decanuclear ruthenium(II) polypyridine complex.<sup>53,54</sup>

Incorporation of the  $\text{Ru}(\text{bpy})_3$  moiety into acyclic, macrocyclic, and calixarene frameworks leads to a new class of anion receptors capable of optical and electrochemical sensing (see (19)).<sup>55</sup> The remarkable reactivity of high-oxidation-state ruthenium and osmium polypyridyl complexes has been recently reviewed by Meyer and Huynh,<sup>17</sup> whereas the significance of polypyridyl complexes as biomimetic models for the photosynthetic reaction center was analyzed by Dürr and Bossmann.<sup>56</sup> The viologen-linked  $[\text{Ru}(\text{bpy})_3]^{2+}$  system has been widely investigated, and a soluble polymer based on a polypyrrole–bisviologen-linked  $[\text{Ru}(\text{bpy})_3]^{2+}$  dyad is now available. The photostability of the dyad network in the presence of oxygen offers new possibilities in photoinduced redox processes (see *Electrochemistry: Applications in Inorganic Chemistry*).<sup>57</sup>

### 5.2.1 Molecular Photovoltaics

The photochemical properties of bipyridine ruthenium compounds are at the origin of impressive results in the field of molecular photovoltaics. In 1991, Grätzel *et al.* prepared a molecular photovoltaic system by coating  $\text{TiO}_2$  with a bipyridine complex linked to the surface

by carboxylate groups (*see Semiconductor Interfaces and Superconductivity*). This system is able to inject one electron into the semiconductor conduction band extremely rapidly after photoexcitation. It is now admitted that the process occurs in the femtosecond time regime. By contrast, the back reaction of the electrons with the oxidized ruthenium complex is slow (microsecond to millisecond timescale). This first dye-sensitized nanocrystalline solar cell gave a conversion yield of 7%. Following this result, hundreds of other complexes have been synthesized and tested, but the polypyridyl–ruthenium complexes remain the precursors of choice for achieving the best photovoltaic performances. The best results are now obtained by complexes (20) and (21), known as N3 and black dye, respectively. The efficiency obtained with the black dye (21) is 10.4% under standard air mass 1.5 reporting conditions. The interaction between the carboxylic group and  $\text{TiO}_2$  is of fundamental importance as the dye is attached via two carboxylates. Projects concerning molecular engineering with judicious substitutions of the carboxylic groups are under investigation. The ultimate goal is the splitting of water into dihydrogen and dioxygen by sunlight.<sup>58,59</sup> In photosynthesis, water oxidation is accomplished by photosystem II (PSII), which is a large membrane-bound protein. Several studies, aimed at mimicking the light-driven oxidation of water accomplished by PSII, involve the use of a photosensitizer, a ruthenium(II) complex incorporating bpy units, linked to manganese complexes (*see Photosynthesis*).<sup>60</sup>

### 5.2.2 Molecular Machines

A special issue devoted to molecular machines appeared in 'Accounts of Chemical Research' in 2001. It reflects the current interest for this field in which ruthenium complexes act as important tools. Molecular machines are characterized by a mobile part and a stationary part. Photochemical and electrochemical inputs can make a machine work, offering the advantage of being switched on and off easily and rapidly. Mechanically interlocked molecules, such as rotaxanes and catenanes, are suitable candidates. Crown ethers, cyclophanes, and calixarenes are representative families of the cyclic

component. The design of even more sophisticated molecular-level machines should open the way to a variety of applications. We have selected three examples to illustrate this fascinating field.

The design of a rotaxane is a synthetic challenge. One strategy is to combine a bifunctional ligand and two different metals, as demonstrated by Sauvage *et al.* The bifunctional ligand containing one dpp and two terpy units is treated with a preformed  $\text{Cu(I)(dpp)}$  macrocyclic complex to afford a prerotaxane complex with pendent terpyridines. The  $[\text{Ru(terpy)}]^{2+}$  is then anchored to the pendent ligands. Selective removal of the cage  $\text{Cu(I)}$  template produces the rotaxane shown as structure (22).<sup>61</sup>

Another recent example also comes from Strasbourg's group that prepared the first rotaxane with a  $[\text{Ru(diimine)}_3]^{2+}$  core. The synthetic scheme consists of a 'threading' step followed by a stopping reaction: a ruthenium bisphenanthroline complex, acting as an axis, is threaded through a 35-membered ring macrocycle incorporating a bpy unit. The pseudorotaxane is shown in structure (23). The length of the threaded ring is too short and an isomer in which the axial ruthenium complex is attached in an exo fashion is also obtained (see structure (24)). A modified strategy has allowed the synthesis of a real rotaxane deriving from (23).<sup>62</sup>

The third example comes from Stoddart's and Balzani's groups. They prepared a photochemically driven molecular-level abacus by a four-step process. The system is made up of a photoactive unit P (a  $[\text{Ru(bpy)}_3]^{2+}$ -type complex serving as a stopper), two different  $\pi$ -electron acceptors  $A_1$  and  $A_2$  playing the role of stations for a  $\pi$ -electron-donor ring R (the BPP34C10 macrocycle), a rigid spacer S, and a tetraarylmethane group as second stopper T. The [2]rotaxane is shown as structure (25). The photochemically driven switching of the ring R between stations  $A_1$  and  $A_2$  is achieved by a mechanism involving a sacrificial electron donor.<sup>63,64</sup>

### 5.2.3 Interaction with DNA

Transition metal complexes can help target DNA sites with specificity, probe DNA, and furnish highly

sensitive diagnostic agents. Metallointercalators contain planar aromatic heterocyclic groups able to insert and stack between the base pairs of double helical DNA (see **Intercalation Chemistry** and **Nucleic Acid–Metal Ion Interactions**). Extensive work was performed by Barton *et al.*, and key features on recognition and reaction of metallointercalators with DNA have been reviewed in 1999.<sup>65</sup> One of the earliest examples concerned  $[\text{Ru}(\text{phen})_3]^{2+}$  existing, like any tris(diimine) ruthenium complex, as a mixture of enantiomers. In order to improve the complex binding affinities for DNA, the search for new ligands favoring intercalation was undertaken. Structures (26–28) are some typical examples. Minor changes in the ligand architecture and electronic structure can lead to profound influences on binding geometries.

The data concerning  $[\text{Ru}(\text{phen})_2(\text{dppz})]^{2+}$  nicely illustrate the concept of ‘molecular light switch’ (dppz for 28). When the complex is bound to DNA, the excited-state lifetime is approximately 200 ns, whereas without bounding, it is only 200 ps. This light-switch effect provides the basis for a valuable photophysical probe of nucleic acids. Luminescent characteristics of the complexes bound to DNA can also be used to illustrate the chiral discrimination associated with binding to the right-handed helix. Direct oxidation of

DNA bases is also obtained by electrochemical activation of  $[\text{Ru}(\text{bpy})_3]^{2+}$ . Recent developments concern the damage to DNA sites from a distance: site damage up to 200 Å away from the site of intercalation of the metal oxidant has been reported (see **Long-range Electron Transfer in Biology**). One of the main challenges now is to use these molecules *in vivo*.<sup>65,66</sup>

The synthesis and properties of Ru(II) nucleosides and oligonucleotides have been recently reported using solid-phase

phosphoramidite chemistry. The first results offer interesting perspectives.<sup>67</sup>

### 5.3 Nitrosyl Ligands

The nitrosyl ligand can be combined with any other ligand (X, OH, H<sub>2</sub>O, CO, PR<sub>3</sub>, acac, NH<sub>3</sub>, cyclam, *N*-aromatic heterocycles, NO<sub>2</sub>, SO<sub>2</sub>, DMSO, etc.) to form a wide range of nitrosyl ruthenium compounds (neutral, cationic, and anionic) with linear or bent NO ligands. This has been recently reviewed by Legzdins *et al.* and Housecroft.<sup>3,68</sup> The organometallic chemistry of nitrosyl ruthenium complexes is very rich, and various alkyl, acyl, alkene, carbene, and allyl complexes are known (see *Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry* and *Ruthenium: Organometallic Chemistry*). The last decade has seen a renewed interest in understanding the chemistry of metal nitrosyl complexes, owing to the participation of NO in a wide range of physiological processes. The coordination and the release of NO by ruthenium dimethylsulfoxide<sup>39</sup> and ruthenium amine<sup>69</sup> complexes have been extensively investigated. Techniques such as X Ray, <sup>15</sup>N NMR, IR, EPR are very useful for determining the mode of bonding (i.e. N is deshielded by up to 450 ppm in bent form as compared to linear NO ligands). Spectroscopic methods associated with electrochemical techniques lead to a better understanding of the NO release mechanism. Studies of the reactivity of nitrosyl complexes are oriented toward reactions involving oxygen transfer to or from nitrosyl ligands and

reduction of coordinated nitric oxide. For example, Shepherd *et al.* have studied, for the first time, a series of NO<sup>+</sup>, NO<sup>•</sup>, and NO<sup>-</sup> [Ru(hedta)]<sup>n-</sup> complexes by keeping a constant ligand–metal environment (see structure (29)). They found that the metal remained in the same oxidation state (II).<sup>68</sup>

The most common geometry displayed by ruthenium nitrosyl complexes is octahedral. However, some square-pyramidal and sawhorse geometries have been characterized. Chloride abstraction from Ru(NO)Cl(CO)(PR<sub>3</sub>)<sub>2</sub> presenting a square-pyramidal geometry leads to [Ru(NO)(CO)(PR<sub>3</sub>)<sub>2</sub>]<sup>+</sup> (30) with a sawhorse structure, as a result of an intramolecular redox process. NO bending modification, from bent to linear, is concomitant with a formal decrease in the ruthenium oxidation state from +II to 0.<sup>68</sup> [Ru(NO)<sub>2</sub>Cl(PPh<sub>3</sub>)<sub>2</sub>]PF<sub>6</sub> was the first complex containing the two modes of binding, that is, linear and bent (Ru–N–O axial, 138° Ru–N–O equat, 178° ν<sub>NO</sub> linear, 1845 cm<sup>-1</sup>; ν<sub>NO</sub> bent, 1687 cm<sup>-1</sup>).

### 5.4 Miscellaneous Nitrogen Ligands

Although they have not yet attracted as much attention as the nitrosyl complexes, a large number of the isoelectronic thionitrosyl ones have been prepared. The most representative family is Ru(NS)Cl<sub>3</sub>L<sub>2</sub>, where L is phosphines, arsines, or stilbines. A linear bonding mode is observed.

We have previously mentioned in Section 4.2 the chemistry developed by Sellmann *et al.*, by using tetradentate or pentadentate 'S4' ligands. The use of such a ligand in nitrosyl ruthenium chemistry allowed the first conversion of a nitrosyl complex into a ruthenium HNO complex (**31**) by addition of NaBH<sub>4</sub> to [Ru(NO)(py<sup>bu</sup>S<sub>4</sub>)]Br. The formation and decomposition of HNO complexes is often invoked in many processes such as combustion of fuels, oxidation of N<sub>2</sub>, reduction of HNO<sub>2</sub>, and so on.<sup>70</sup>

A large number of compounds with N-donor heterocyclic ligands have been prepared. Ruthenium complexes incorporating phthalocyanine or aza-macrocyclic ligands are known (*see Macrocylic Ligands*). In comparison to porphyrin chemistry, metallocalens and metallocalophens have received little attention, despite an easier synthetic access. A series of mononuclear and binuclear ruthenium derivatives with N<sub>2</sub>O<sub>2</sub> Schiff base ligands are available. Some of them can act as supramolecular synthons.<sup>71</sup>  $\alpha$ -Amino acids stabilize Ru(bpy)<sub>2</sub> moieties to produce the corresponding cations. The amino acid acts as a bidentate N,O-donor, leading to a five-membered metallocycle. A six-membered imine Ru(III) metallocycle was obtained by reduction of an oxime with RuCl<sub>2</sub>(PPh<sub>3</sub>)<sub>3</sub>.<sup>72</sup>

The chemistry of ruthenium complexes incorporating edta, or related ligands such as pac, is generally based on substitution reactions of the water ligand present in the coordination sphere of the metal. The catalytic properties of these complexes in various organic transformations have been exploited, including electrocatalytic studies.<sup>73</sup>

The trispyrazolyl borate chemistry (*see Boron–Nitrogen Compounds*) of ruthenium has prospered mainly during the last decade and is mostly restricted to ruthenium (II). The most common coordination mode of the tripyrazolylborates (Tp) ligand is the  $\kappa^3(N,N',N'')$  mode (*see structure (32)*), but there are also some examples of the  $\kappa^3(N,N',H)$  and  $\kappa^2(N,H)$  (*see structure (33)*) modes.<sup>74,75</sup> Two principal areas have been explored: the search for new polyhydrides and the organometallic reactivity of TpRu precursors. A rare example of a stable bis(dihydrogen) complex Tp\*RuH(H<sub>2</sub>)<sub>2</sub> (**32**) could be isolated. Its chemistry is dominated by the electrophilic character of the hydride and dihydrogen ligands, as illustrated by the rapid exchange in deuterated solvents or by the

absence of protonation by acids. A series of substituted complexes [Tp\*RuH(H<sub>2</sub>)L] could be obtained (L = PCy<sub>3</sub>, tetrahydrothiophene (THT), py, NHEt<sub>2</sub>). (**32**) catalyzes the reduction of ketones in mild conditions either by H<sub>2</sub> or by H<sub>2</sub> transfer from alcohols.<sup>74</sup> Cationic Tp complexes of the general formula [TpRu(H<sub>2</sub>)LL']<sup>+</sup> were obtained by protonation of the corresponding hydrides.<sup>76</sup> TpRuCl(cod) is a precursor of choice for inducing a rich organometallic reactivity, which has been reviewed. Tp complexes accommodating carbon single or double bonds have been obtained and various catalytic coupling reactions were performed.<sup>77</sup> Another precursor of choice is TpRuCl(PPh<sub>3</sub>)<sub>2</sub>, whose synthesis has been described in 'Inorganic Synthesis'.<sup>78</sup> BpRuH(cod) is a valuable precursor for a series of bispyrazolyl BpRu complexes in which the Bp ligand is able to coordinate with the ruthenium using three different modes:  $\kappa^3(N,N',H)$ ,  $\kappa^2(N,H)$ , or  $\kappa^2(N,N')$ .<sup>79</sup>

Nitriles, specifically acetonitrile, play an important role as solvents in inorganic chemistry. Nitriles are therefore found as co-ligands in various ruthenium complexes. [RuCl<sub>2</sub>(MeCN)<sub>4</sub>] is readily prepared by reduction of RuCl<sub>3</sub>·3H<sub>2</sub>O in acetonitrile using different methods, a convenient one being the use of dihydrogen and Adam's catalyst (PtO<sub>2</sub>). This complex is an excellent well-defined ruthenium(II) starting material.

## 6 RUTHENIUM COMPLEXES OF PHOSPHORUS-DONOR LIGANDS (*See P-donor Ligands*)

The chemistry of ruthenium (II) complexes incorporating P-donor ligands, particularly phosphines and diphosphines, is flourishing. This class of compounds has given rise to a versatile organometallic reactivity. They are also found in many catalytic cycles, but decoordination of the phosphine from the coordination sphere of the metal is often required for the catalysis to proceed.

Scheme 3

### 6.1 Triphenylphosphine Derivatives

The most important phosphine derivative of ruthenium is RuCl<sub>2</sub>(PPh<sub>3</sub>)<sub>3</sub> (**34**), which is readily prepared from RuCl<sub>3</sub>·3H<sub>2</sub>O and PPh<sub>3</sub> in methanol. This procedure is, however, not generally used since large basic phosphines (P<sup>i</sup>Pr<sub>3</sub>, PCy<sub>3</sub>) lead to alcohol decarbonylation, whereas trichloro-bridged ruthenium(III) dimers are obtained by using small basic phosphines such as PMe<sub>2</sub>Ph. RuCl<sub>2</sub>(PPh<sub>3</sub>)<sub>3</sub> (**34**)

has found wide use as a precursor for other ruthenium(II) complexes and as a catalyst precursor for various reactions, essentially associated with hydrogenation or hydrogen transfer (see *Hydrogenation & Isomerization of Alkenes*). RuCl<sub>2</sub>(PPh<sub>3</sub>)<sub>3</sub> can undergo three types of elementary reactions: (1) nucleophilic substitution of chloride groups, (2) addition of two-electron donor ligands, and (3) substitution of triphenylphosphine ligands and, usually, a combination of the three of them. Selected examples are shown in Scheme 3. The structure of (**34**) can be considered as octahedral, one hydrogen atom of a phenyl ring of a phosphine occupying the vacant coordination site. However, the Ru–H distance is long (2.59 Å), indicating a very weak agostic interaction. Additional structural information can be gained on (**34**) and related complexes by <sup>31</sup>P CP/MAS NMR spectroscopy.<sup>80</sup> It is remarkable that the use of ortho-methyl substituents has allowed the isolation of the first complex with two Ru···H–C agostic interactions RuCl<sub>2</sub>{PPh<sub>2</sub>(2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>}<sub>2</sub> (**35**), as demonstrated by NMR and X ray.<sup>81</sup> RuCl<sub>2</sub>(PPh<sub>3</sub>)<sub>3</sub> was one of the first transition metal complexes shown to activate dihydrogen heterolytically. The mechanism involves deprotonation from a transient unstable dihydrogen complex (see *Dihydrogen Complexes & Related Sigma Complexes*). As shown in Scheme 3, some or all of the phosphine ligands can be substituted by various ligands. This includes diop, which leads to [(RuCl<sub>2</sub>(diop))<sub>2</sub>(μ-diop)], and various bidentate phosphines (L<sub>2</sub>), leading to complexes of the general formula RuCl<sub>2</sub>L<sub>2</sub>(PPh<sub>3</sub>)<sub>2</sub> or RuCl<sub>2</sub>(L<sub>2</sub>)<sub>2</sub>.

Phosphine substitution by water-soluble ligands has been used for the design of new catalysts that could be recovered from the aqueous phase. Extensive intra- and intermolecular hydrogen bonding are responsible of the high water solubility of a secondary–tertiary hydroxymethylphosphine complex, [Ru{P(CH<sub>2</sub>OH)<sub>3</sub>}<sub>2</sub>{P(CH<sub>2</sub>OH)<sub>2</sub>H}<sub>2</sub>Cl<sub>2</sub>}].<sup>82</sup> The most important class of water-soluble ligands incorporates sodium sulfonate groups, with tppts being the preferred ligand. The complexes RuCl<sub>2</sub>(tppts)<sub>3</sub>, [RuCl<sub>2</sub>(tppts)<sub>2</sub>]<sub>2</sub>, RuHX(tppts)<sub>3</sub> (X = Cl, I, OAc), and RuH<sub>2</sub>(tppts)<sub>4</sub> can be prepared, and these display a reactivity in water similar to that of triphenylphosphine complexes in organic solvents, with, in some cases, an increase in activity and enhanced regioselectivity.<sup>83</sup>

The reaction of RuCl<sub>2</sub>(PPh<sub>3</sub>)<sub>3</sub> with diphenylcyclopropene led to the isolation of the alkylidene complex, whereas

addition of an aryldiazoalkane allowed the formation of the benzylidene catalyst (see Scheme 4). These complexes are the first members of the  $L_2X_2Ru=CHR$  family that has led to impressive developments, mainly by R. Grubbs' group, in the field of olefin metathesis (see *Carbene Complexes; Metathesis Polymerization Processes by Homogeneous Catalysis; Organic Synthesis Using Metal-mediated Metathesis Reactions*, and *Ruthenium: Organometallic Chemistry*).<sup>84</sup>

$RuCl_2(PPh_3)_3$  and  $RuHCl(PPh_3)_3$  display a large catalytic activity.  $RuHCl(PPh_3)_3$  is one of the most active alkene hydrogenation catalysts, while  $RuCl_2(PPh_3)_3$  is of special use for hydrogen transfer reactions, in particular, the hydrogenation of bulky or functional compounds (equation 1) (see *Hydrogenation & Isomerization of Alkenes*).  $RuCl_2(PPh_3)_3$  is also a catalyst for hydrosilation (see *Hydrosilation Catalysis*), although it is slow; chlorocarbon addition to alkenes; and even oxidation.

## 6.2 Diphosphine Complexes

A large number of bidentate phosphine ligands accommodate ruthenium in various oxidation states and in mono- or dinuclear structures. Some can be found in the same complex as both a monodentate and a bidentate ligand. The number of Ru(III) complexes is rather limited, but a series of  $RuCl_3(P-P)L$  complexes have been prepared with  $P-P = dppe$  or  $diop$ . In the case of  $L = H_2O$ , the X-ray structure shows that the aqua ligand forms hydrogen bonds with two chloro ligands of a neighboring molecule (see *Hydrogen Bonding & Dihydrogen Bonding*). The exchange coupling between the two Ru(III) centers is evidenced by ESR data.<sup>85</sup> The most important family is represented by complexes of the general formulation  $RuX_2(L-L)_2$ . Since the earlier work by

Chatt *et al.*, a wide range of cis and trans  $RuX_2(L-L)_2$  complexes have been synthesized by the reaction of  $RuCl_3 \cdot 3H_2O$ ,  $RuCl_2(PPh_3)_3$ ,  $RuCl_3(py)_4$ , or  $K_2RuCl_5(OH_2)$  with  $L-L$  in alcoholic solution ( $L-L = dppe, dppe, dppp, dmpe$ , etc.). Elegant studies involving laser flash photolysis and matrix isolation show the importance of  $RuH_2(L-L)_2$  complexes in C-H bond activation. Dihydrogen loss and formation of square-planar  $Ru(L-L)_2$  intermediates are induced by photolysis (see *Photochemistry of Transition Metal Complexes and Alkane Carbon-Hydrogen Bond Activation*).<sup>86</sup> A few ruthenium complexes incorporating trans-spanning diphosphine ligands have been synthesized. However, the advantages of using such peculiar ligands remain to be demonstrated.<sup>87</sup>

The most significant industrial applications come from Noyori *et al.*, who have described ruthenium complexes bearing chiral BINAP ligands (see *Asymmetric Synthesis by Homogeneous Catalysis*).<sup>88,89</sup> Noyori shared the Nobel Prize for chemistry in 2001 with Knowles and Sharpless for his achievements in asymmetric catalysis. BINAP-Ru dihalide catalysts have a very wide scope in industrial applications. The first key complexes, (36) and (37), were obtained in good yield by the reaction of  $[RuCl_2(cod)]_n$  with (*S*)- or (*R*)-BINAP and triethylamine at 110 °C, followed by final treatment with sodium acetate in *t*-butyl alcohol at 80 °C. The crystal structure of  $[Ru(OCO-tBu)_2\{(S)-BINAP\}]$  indicates a C<sub>2</sub> chirality. They are very effective catalysts in the hydrogenation of alkenes or ketones (see *Hydrogenation & Isomerization of Alkenes*). For example, the synthesis of the anti-inflammatory drug Naproxen is achieved quantitatively in 97% optical yield.

(36) (*R*)-BINAP Ru<sup>II</sup> complex

(37) (*S*)-BINAP Ru<sup>II</sup> complex

Scheme 4

These Ru-catalysts provide a practical way to prepare an intermediate for prostaglandin synthesis. Antibacterials and carbapenem antibiotics are now produced industrially. New achievements have been obtained with the introduction of diamine ligands, leading to the asymmetric synthesis of various pharmaceutical compounds. The catalyst mixture, as shown in Scheme 5, consists of a complex of the form  $RuCl_2(\text{diamine})(\text{diphosphine})$  with an alkoxide base, dihydrogen, and ketone in 2-propanol (see *Asymmetric Synthesis by Homogeneous Catalysis*).<sup>88,89</sup> An in-depth mechanistic study was performed by Morris' group, leading to a better understanding of the catalytic cycle as depicted

Scheme 5

Scheme 6

in Scheme 6.<sup>90</sup> The use of the water-soluble dibenzofuran-based diphosphine ligands (BIFAPS) leads to high ee's in Ru-catalyzed hydrogenations (similar to BINAP).<sup>91</sup>

### 6.3 Polydentate Phosphines, Pincer Ligands, Phosphorus Heterocycles, and Phosphorus-based Hemilabile Ligands

The use of polydentate phosphines has received a renewed interest, with the search for new families of polyhydrides or molecular dihydrogen complexes (*see Dihydrogen Complexes & Related Sigma Complexes*). For example, PP<sub>3</sub>RuCl<sub>2</sub>

(PP<sub>3</sub> = P(CH<sub>2</sub>CH<sub>2</sub>PPh<sub>2</sub>)<sub>3</sub>) was used as an entry to mono- and polyhydride ruthenium(II) complexes. The Ru(II) complex [(triphos)RuH(BH<sub>4</sub>)] with the tripodal ligand triphos reacts with KO<sup>t</sup>Bu to form the ruthenate complex [K(triphos)RuH<sub>3</sub>]. The compound catalyzes benzothiophene hydrogenolysis into 2-ethylthiophenol.<sup>92</sup> Various ruthenium complexes containing a triphosphine ligand deriving from PPh(CH<sub>2</sub>CH<sub>2</sub>PR<sub>2</sub>)<sub>2</sub> and PPh(CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>PR<sub>2</sub>)<sub>2</sub> have been prepared, including chiral ligands. The ability of the polydentate phosphine to control the stereochemistry and coordination number of the resulting complexes, and the presence of hydride and/or dihydrogen ligands provide access to unusual chemical (homogeneous catalysis) and structural properties.<sup>93</sup> A series of complexes incorporating a rigid allene-bridged polyphosphine exhibit room-temperature luminescence.<sup>94</sup>

During the past decade, the chemistry of complexes incorporating phosphine-based pincer ligands has rapidly developed. Most of these ligands are cyclometalated and thus will not be reviewed in this chapter. However, various complexes incorporating PNP ligands have been prepared and show interesting spectroscopic and catalytic properties (*see Phosphorus–Nitrogen Compounds*).<sup>3,95,96</sup> The reactivity of the ligand (R<sub>2</sub>PCH<sub>2</sub>SiMe<sub>2</sub>)<sub>2</sub>N– on ruthenium has now appeared. The most striking result is the characterization of a four-coordinate, planar Ru(II) displaying a triplet state as a consequence of the low-coordination number and the lack of agostic interactions (see structure (38)).<sup>97</sup>

2,2'-Biphosphinines (tmbp) are analogous to bipyridines, albeit containing two phosphorus atoms (*see Phosphorus: Organophosphorus Chemistry*). These ligands behave as excellent  $\pi$  acceptors, and chloro ruthenium complexes incorporating one or two tmbp could be isolated. The most significant result was obtained using the reduced ligand, and stabilization of a dianionic Ru complex was achieved. The complex [Ru(tmbp)<sub>2</sub>][Li(THF)<sub>3</sub>]<sub>2</sub> (39) presents a square-planar geometry with electrostatic interaction between Ru and Li centers.<sup>98</sup>

The synthesis of hemilabile ligands for the design of new catalysts is a very active area of research. Hemilabile ligands act as chelating ligands with one strongly and one weakly bonding group (see Structures (40) and (41)). The

weakly bonding group can be easily displaced, offering new opportunities for catalytic applications. In this context, the chemistry of mixed phosphorus chelating ligands has been particularly examined (see *Mixed Donor Ligands*). The most common type concerns the phosphorus–oxygen association, while systems with phosphorus–sulfur or phosphorus–nitrogen ligands are more limited. A common reaction involves  $\text{PPh}_3$  substitution by the hemilabile ligand L from  $\text{RuCl}_2(\text{PPh}_3)_3$  or from  $\text{RuHCl}(\text{PPh}_3)_3$ .<sup>99</sup>

## 7 RUTHENIUM COMPLEXES OF GROUP-14 LIGANDS

Carbonyl complexes and complexes incorporating isocyanides are generally considered to be organometallic and are not reviewed in this article (see *Ruthenium: Organometallic Chemistry* and *Carbonyl Complexes of the Transition Metals*). In contrast, cyanides are regarded as inorganic complexes (see *Cyanide Complexes of the Transition Metals*).  $\text{K}_4[\text{Ru}(\text{CN})_6]$  was first prepared in 1896 through the action of KCN on  $\text{K}_2[\text{RuO}_4]$  or  $\text{RuCl}_3 \cdot x\text{H}_2\text{O}$ . Hexacyanide is found as a tetraanion with various cations or even as the tetracid. This complex undergoes a variety of substitution reactions and gives rise to cyano-bridged polynuclear compounds, either homo- or heteronuclear. Among the substitution reactions, a lot of interest has been devoted to the photophysical properties of mixed cyanide/diimine complexes.<sup>100</sup>

Silane activation by ruthenium complexes has been a field of intense activity over the past decade. This was made possible thanks, in particular, to the fantastic progress achieved in NMR and X-ray techniques, as well as in DFT calculations. A number of ruthenium complexes incorporating a silicon-attached ligand (see *Silicon: Inorganic Chemistry*) are now available, with several variations of interactions between the silane and the metal.<sup>101</sup> Full oxidative addition can be observed leading to Si–H bond breaking and formation of the corresponding silyl or bis(silyl) complexes (42).<sup>102</sup> Arrested addition leads to the isolation of  $\sigma$ -silane complexes, analogous to the  $\sigma$ -dihydrogen complexes (see *Dihydrogen Complexes & Related Sigma Complexes*).<sup>103,104</sup> Bridging and terminal  $\text{SiR}_2$  groups (silylene complexes with  $\text{Ru}=\text{Si}$

bonds) can also be isolated.<sup>101</sup> The factors that promote the formation of the different structures are multiple, and the substituents on silicon and the electron density on ruthenium play a crucial role. Ruthenium complexes incorporating one, and even two,  $\sigma$ -Si–H bonds are now available, as shown by the general structure  $[\text{RuH}_2\{(\eta^2\text{-HSiR}_2)_2\text{X}\}(\text{PCy}_3)_2]$  (43).<sup>104</sup> It is important to note that in these bis(silane) complexes, the establishment of secondary interactions between the silicon atoms and the classical hydrides stabilize the complexes and promote the unusual cis position of the bulky phosphines.<sup>105</sup>

Unusual redistribution at silicon is observed by adding secondary silanes to the bis(dihydrogen) complex  $\text{RuH}_2(\text{H}_2)_2(\text{PCy}_3)_2$  (see Section 8).<sup>106</sup> The complex  $[\text{RuH}_2(\text{PR}_3)_2]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{:}\eta^2\text{:}\eta^2\text{-SiH}_4)$  (44) ( $\text{R} = \text{Cy}, \text{ }^i\text{Pr}$ ) is isolated with the  $\text{SiH}_4$  ligand trapped in between the two metals. The silane is coordinated to the metals via four  $\sigma$ -Si–H bonds. Each interaction involves  $\sigma$ -donation to a ruthenium and back-bonding from the other ruthenium. A second redistribution process is observed after addition of an excess of  $\text{HSi}(\text{OMe})_3$  to (44). The dinuclear complex (45) is isolated, and the data show that the frontiers between true  $\sigma$ -Ru–H–Si interactions and more delocalized systems are not clear-cut (see Scheme 7).<sup>106</sup> Silyl and  $\sigma$ -silane complexes find important applications as catalyst precursors for Si–C coupling in hydrosilylation, dehydrogenative silylation, and dehydrocoupling for the formation of vinyl silanes and oligomeric carbosilanes, respectively (see *Hydrosilylation Catalysis*; *Carbon–Carbon & Carbon–Heteroatom Activation*, and *Polysiloxanes & Polysilanes*).

In comparison to Si, much less work has been published concerning Ge or Sn (see *Germanium: Organometallic Chemistry* and *Tin: Organometallic Chemistry*). The complex  $\text{Ru}(\text{GeMe}_3)_2(\text{PMe}_3)_4$  is an effective catalyst for the production

Scheme 7

of high molecular weight polygermanes from  $\text{HGeMe}_3$ .<sup>107</sup> A number of complexes incorporating the  $\text{RuSnR}_3$  moiety have been prepared. A rare example of a complex (**46**) containing a four-electron tridentate tin donor ligand was isolated,<sup>108</sup> and more recently, the complex  $\text{Ru}(\text{SnPh}_3)_2(\text{P}_2\text{C}_2\text{Ph}_2)_2$  with two  $\text{SnPh}_3$  units and a bis(diphosphabutadiene) ligand was reported.<sup>109</sup>

## 8 RUTHENIUM HYDRIDE COMPLEXES (See *Hydride Complexes of the Transition Metals and Dihydrogen Complexes & Related Sigma Complexes*)

The rich chemistry of ruthenium hydride developed rapidly after the preparation of  $\text{RuHCl}(\text{PPh}_3)_3$ .<sup>1</sup> The polyhydrides  $\text{RuH}_2(\text{PPh}_3)_4$  and  $\text{RuH}_4(\text{PPh}_3)_3$  were synthesized by reduction of  $\text{RuCl}_2(\text{PPh}_3)_3$  with hydride donor reagents such as  $\text{NaBH}_4$ . The dihydride  $\text{RuH}_2(\text{PPh}_3)_4$  can be used as an interesting alternative to conventional Lewis acid and base catalysts, as proven by its specific activity for nitrile activation.<sup>110</sup> Numerous hydrido derivatives containing other anionic functional ligands were prepared, either by anionic substitution of chloride on  $\text{RuHCl}(\text{PPh}_3)_3$  or by reaction of the polyhydrides with acidic compounds (equation 2). The synthesis of hydride complexes, using  $(\text{BH}_4)^-$  or  $(\text{AlH}_4)^-$ , may involve the formation of  $\text{Ru-BH}_4$  or  $\text{Ru-AlH}_4$  derivatives with one or two bridging hydrides. The method of preparation by reduction of chloride precursors has allowed the synthesis of derivatives of alkyl phosphines with a small cone angle, for example,  $\text{RuH}_2(\text{P}^i\text{Bu}_3)_4$ . However, for bulky alkylphosphine derivatives, the preparation involves hydrogenation of the ruthenium(0) precursor  $\text{Ru}(\text{C}_8\text{H}_{10})(\text{C}_8\text{H}_{12})$  (see equation 3).

The discovery by Kubas of the coordination of dihydrogen without dissociation gave a new impetus to ruthenium hydride chemistry (see *Dihydrogen Complexes & Related Sigma Complexes*).<sup>111</sup> As mentioned already in Section 7, considerable progress in NMR and X-ray techniques have allowed better characterization of many compounds and, in particular, better discrimination between a dihydride or

a dihydrogen formulation. In addition, many more theoretical studies are now performed on polyhydrides and  $\sigma$ -complexes. Key information is thus gained, not only on the structures and energetics but also on the dynamic processes that are common in these systems.<sup>105,112</sup>  $\text{RuH}_4(\text{PPh}_3)_3$  was mentioned as early as 1976 by Ashworth and Singleton as possibly containing undissociated dihydrogen. This was confirmed 10 years later by Crabtree and Hamilton who reformulated it as  $\text{RuH}_2(\text{H}_2)(\text{PPh}_3)_3$ . Similarly,  $\text{RuH}_6(\text{PCy}_3)_2$  was reformulated as  $\text{RuH}_2(\text{H}_2)_2(\text{PCy}_3)_2$  (**47**), a rare example of a thermally stable bis-dihydrogen complex (see equation 3). This complex displays a versatile reactivity, in some cases, similar to  $\text{RuH}_2(\text{H}_2)(\text{PPh}_3)_3$  and  $\text{RuH}_2(\text{N}_2)(\text{PPh}_3)_3$  (see Scheme 8). In particular, it reacts with halocarbons and thiols to give the corresponding 16-electron dihydrogen complexes,  $\text{RuH}(\text{H}_2)\text{X}(\text{PCy}_3)_2$  ( $\text{X} = \text{Cl}, \text{I}, \text{SR}$ ). The chemistry of (**47**) was reviewed in 1998 before the report of its X-ray crystal structure in 2000.<sup>74,113</sup> The reactivity of (**47**) with silanes leading to the formation of new  $\sigma$ -silane complexes and to interesting catalytic applications has been briefly described in Section 7.<sup>103–106</sup> It was also possible to activate various boranes, both stoichiometrically and catalytically (see *Boron Hydrides; Boron: Organoboranes, and Hydroboration Catalysis*).<sup>114,115</sup> Remarkably, a complex incorporating two boron-attached ligands coordinated with two different bonding modes,  $[\text{RuH}\{(\mu\text{-H})_2\text{Bpin}\}(\sigma\text{-HBpin})(\text{PCy}_3)_2]$ , was isolated and proved to be an active species for catalytic formation of vinyl boranes or for selective hydroboration of olefins.<sup>114</sup> (**47**) is also a catalyst precursor for the hydrogenation of S- and N-heteroaromatic substrates (see *Hydrodesulfurization & Hydrodenitrogenation*).<sup>31,116</sup> The presence of labile dihydrogen ligands is the key factor in the ability of (**47**) to catalyze, at room temperature, the Murai reaction (C–C bond coupling of an olefin with a functionalized aromatic compound. See *Carbon–Carbon & Carbon–Heteroatom Activation* and *Ruthenium: Organometallic Chemistry*). In the case of acetophenone, the resulting orthometalated complex  $\text{RuH}(\text{H}_2)(o\text{-C}_6\text{H}_4\text{C}(\text{O})\text{Me})(\text{PCy}_3)_2$  displays remarkable spectroscopic properties as exchange couplings between the hydride and the coordinated dihydrogen molecule can be detected by NMR.<sup>117</sup>

Ruthenium polyhydride complexes containing monophosphaferrocenes are now available.<sup>118</sup> In contrast to Cp ruthenium chemistry, the use of a trispyrazolyborate ligand favors the formation of dihydrogen structures: the chemistry of Tp

Scheme 8

and Bp ruthenium complexes has been briefly described in Section 5.4.<sup>74–79</sup>

Anionic polyhydride derivatives were obtained by reaction of potassium naphthalenide with RuHCl(PPh<sub>3</sub>)<sub>3</sub> in THF. Addition of H<sub>2</sub> yields the trihydride [RuH<sub>3</sub>(PPh<sub>3</sub>)<sub>3</sub>]<sup>–</sup>, whereas the intermediacy of a diphenylbutadiene derivative is necessary to reach the pentahydride [RuH<sub>5</sub>(PPh<sub>3</sub>)<sub>2</sub>]<sup>–</sup> after elimination of one phosphine ligand. A one-pot reaction was obtained by using a mixture of RuCl<sub>3</sub>/2.5 P<sup>i</sup>Pr<sub>3</sub>, KH, and a crown ether under a dihydrogen atmosphere. Interion proton hydride NH<sub>2</sub>⋯HRu interactions exist in the salts [K(Q)][RuH<sub>5</sub>(P<sup>i</sup>Pr<sub>3</sub>)<sub>2</sub>] when Q is 1-aza-18-crown-6 or 1,10-diaza-18-crown-6.<sup>119</sup>

Cationic derivatives are prepared by protonation (which can lead to dihydrogen evolution) or by halide abstraction in the presence of dihydrogen. The cations [RuH<sub>3</sub>L<sub>4</sub>]<sup>+</sup> and [RuH<sub>5</sub>L<sub>3</sub>]<sup>+</sup> can be prepared by one of these methods. Most of the [RuH<sub>3</sub>L<sub>4</sub>]<sup>+</sup> complexes have now been reformulated as [RuH(H<sub>2</sub>)L<sub>4</sub>]<sup>+</sup>. An important class of hydride derivatives contains chelating phosphorus-donor groups. Thus, the neutral RuHX(L<sub>2</sub>)<sub>2</sub> (X = H, Cl; L<sub>2</sub> = dppe, dppe, dcype, etc.) can adopt a cis or a trans configuration, but the corresponding cationic dihydrogen species ([RuX(H<sub>2</sub>)(L<sub>2</sub>)<sub>2</sub>]<sup>+</sup>) all display a trans configuration. These compounds were extensively studied, and [RuH(H<sub>2</sub>)(dppe)<sub>2</sub>]<sup>+</sup> (48) is one of the few complexes characterized by a neutron diffraction structure.<sup>120</sup> Dicationic complexes, as shown in structure (49), can also be prepared, and they display even more acidic properties than many cationic complexes.<sup>121</sup> The use of an

acidic dihydrogen ruthenium complex as catalyst results in heterolytic cleavage of H<sub>2</sub> and, for example, in catalytic hydrogenolysis of trimethylsilyl enol ethers.<sup>122</sup> A review was published in 1998 on the properties of dihydrogen complexes as homogeneous reduction catalysts (see *Hydrogenation & Isomerization of Alkenes*).<sup>123</sup> NMR methods play a major role in the characterization of polyhydrides (*J*<sub>H–D</sub>, *T*<sub>1</sub>; rate of intramolecular exchange; rate of exchange with other incoming ligands). The parahydrogen-induced polarization (PHIP) method is a relatively new NMR technique that can also bring valuable information on the detection of intermediates. It can be used as a mechanistic probe in highly fluxional systems, as was illustrated in ruthenium hydride carbonyl systems.<sup>124</sup>

(48)

(49)

Unusual ruthenium porphyrin dihydrogen complexes were also obtained.<sup>111</sup> Dinuclear hydride or dihydrogen complexes generally result from the dimerization of hydride and/or chloride precursors. A number of bioctahedral complexes of central core Ru(μ-X)<sub>3</sub>Ru have thus been prepared. The properties of the dinuclear complex [RuHCl(P<sup>i</sup>Pr<sub>3</sub>)<sub>2</sub>]<sub>2</sub> have been extensively studied by Caulton's group, and a rich organometallic chemistry has been reported.<sup>125</sup> Ruthenium hydride complexes have been used to prepare heterobimetallic complexes. Three strategies have been employed: (1) use of a ruthenium anion and reaction with transition metal chloride derivative or vice versa, (2) addition of Lewis acidic cations to ruthenium hydrides, and (3) use of bridging ligands. The mixture of *cis*- and *trans*-RuH<sub>2</sub>(dppm)<sub>2</sub> is, for example, able to react with a variety of metallic fragments to yield mono- or bis-dppm-bridged hydrido species. An unusual example of a ruthenium–iridium complex, a mixed hydrido-alkoxide bridge, was reported.<sup>126</sup>

Hydrogen bonding is a well-known phenomenon that has led to major developments during the last decade in the field of polyhydrides. The formation of the so-called dihydrogen bond (M–H⋯H–X) can occur intermolecularly between a hydride and a weak acid (see equation 4) or intramolecularly between a hydride and a pendant ligand with an NH or OH group. This type of interaction is very important as it may control reactivity and selectivity in solution. A few examples have appeared in ruthenium chemistry.<sup>127,128</sup>

## 9 POLYNUCLEAR COMPLEXES OF RUTHENIUM

The chemistry of ruthenium carbonyl clusters is presented in *Ruthenium: Organometallic Chemistry* and *Polynuclear Organometallic Cluster Complexes*, so the subject of metal particles deposited on supports will not be described in this article (see *Ruthenium: Organometallic Chemistry* and *Polynuclear Organometallic Cluster Complexes*). The field concerning giant clusters and the molecular chemistry of metal particles in organic solutions has grown rapidly during the last decade. The ruthenium complex  $\text{Ru}(\text{C}_8\text{H}_{10})(\text{C}_8\text{H}_{12})$ , as shown by Chaudret *et al.*, has been found to be a useful precursor for the controlled synthesis of well-dispersed nanoparticles stabilized by polymers or various ligands. Recent developments have shown that some of these compounds may be viewed as large inorganic clusters composed of a core of a few nanometers adopting the hcp structure of bulk ruthenium and a surface accommodating both ancillary ligands such as amines and thiols as well as active ligands such as hydrides. These species are active catalysts, in particular, for arene hydrogenation.<sup>129,130</sup> It is, in general, still difficult to distinguish between homogeneous and colloidal catalysis in such systems, although significant progress has recently been made, in particular, by Finke.<sup>131</sup>

## Abbreviations

acac = Acetylacetonate; allyl =  $\eta^3$ -C<sub>3</sub>H<sub>5</sub>,  $\eta^3$ -C<sub>3</sub>R<sub>5</sub>; arene =  $\eta^6$ -C<sub>6</sub>R<sub>6</sub>; bpy = 2,2'-bipyridine; cod = 1,5-cyclooctadiene; cot = Cyclooctatetraene; Cp = Cyclopentadiene (C<sub>5</sub>H<sub>5</sub>); Cp\* = Pentamethylcyclopentadiene (C<sub>5</sub>Me<sub>5</sub>); dmbpy = 4,4'-dimethyl-2,2'-bipyridine; dppm = (diphenylphosphino) methane; *p*-cymene = 1-isopropyl-4-methyl-C<sub>6</sub>H<sub>4</sub>; dad = Diazadienes, RN=CR'-CR'=NR; quin = 8-quinolate; nbd = Norbornadiene; OTf = Trifluoromethanesulfonate OTs = Tosylate; PPN = (Ph<sub>3</sub>P)<sub>2</sub>N<sup>+</sup>; RuCl<sub>3</sub> = RuCl<sub>3</sub>·3H<sub>2</sub>O (approximate); tmbpy = 4,4',5,5'-tetramethyl-2,2'-bipyridine.

## 1 INTRODUCTION

Unlike iron, whose organometallic chemistry dates from the end of the nineteenth century (see **Iron: Organometallic Chemistry**), that of its second-row transition metal congener ruthenium had to wait for the discovery of the sandwich compound ferrocene in 1951 (see *Ferrocene*). The impetus from that breakthrough stimulated all areas of organometallic research, and ruthenocene was reported the very next year.<sup>1</sup> More so than in its coordination chemistry (see **Ruthenium: Inorganic & Coordination Chemistry**), it has become apparent that the organometallic chemistry of ruthenium has many features in common both with iron and with its heavier analog osmium (see **Osmium: Organometallic Chemistry**). Thus, many complex types and reactions that are discussed

below have counterparts with either iron or osmium or both. As is the case in all transition element groups, there is a tendency for substitution or addition (see *Oxidative Addition*) and elimination (see *Reductive Elimination*) reactions to be slower when proceeding down a group in the periodic table. The middle elements, in particular ruthenium and rhodium, profit from this trend, for example, hydride (see *Hydrides*) and alkyl bonds (see *Alkyl Complexes*) are generally more stable and consequently more abundant in ruthenium species than in analogous structures of iron. Conversely, rigid structures have been found in osmium complexes in cases where the ruthenium analogs are either unstable or highly fluxional (see *Fluxional Molecule*). Thus, ruthenium complexes in many instances are more stable than those of iron, yet are more mobile than the osmium equivalents.

Whereas the chemistry of the metallocenes (see *Metallocene Complexes*) is rather similar for the three elements, differences are obvious in their carbonyl chemistries (see *Carbonyl Compound*), which for ruthenium and osmium are based principally on the dodecacarbonyl M<sub>3</sub>(CO)<sub>12</sub>. The pentacarbonyl, a basic material for the carbonyl chemistry of iron, is readily available from daylight photolysis of Ru<sub>3</sub>(CO)<sub>12</sub> (**1**) under CO in solution, but is far less common. Furthermore, carbonyl halides have played a role in the carbonyl chemistry of ruthenium, but analogous compounds of iron or even osmium are less frequently used. Among the iron group metals, cluster carbonyls that incorporate additional main group atoms, mostly hydrogen, carbon, and nitrogen, are broadly similar, although osmium shows the greatest diversity of compounds.

Owing to its higher position in the spectrochemical series (see *Spectrochemical Series*), ruthenium responds more strongly to changes in ligand field (see *Ligand Field Theory*) than iron. Consequently, the higher oxidation states Ru<sup>III</sup> and Ru<sup>IV</sup>, which are abundant in the coordination chemistry of the element, become strongly oxidizing in the presence of acceptor ligands, and are transformed into Ru<sup>II</sup> (or even Ru<sup>I</sup> or Ru<sup>0</sup>) by mild reducing agents, such as alcohols. This property has been exploited in the synthesis of carbocyclic and alkenic  $\pi$ -complexes (see *Alkene Complexes*) of ruthenium where the halide RuCl<sub>3</sub> is treated with ligand or ligand precursors in alcohols with or without additional reducing agents. Hydrogenation/dehydrogenation reactions (see *Hydrogenation*) of poly- and cycloalkenic ligands are frequently observed in these reactions under mild conditions; a stable 18 valence electron coordination environment (see *Eighteen Electron Compounds*) is thereby produced.

The common starting material for nearly all preparations of ruthenium is a hydrated chloride (RuCl<sub>3</sub>) of approximate composition RuCl<sub>3</sub>·3H<sub>2</sub>O, containing 36–42% Ru. Although the material from most sources is not very pure, for example, containing nitrosyls from prior contact with nitric acid, the presence of impurities in most cases is not a serious problem and the yields of conversion of 'RuCl<sub>3</sub>·3H<sub>2</sub>O' can be nearly quantitative based on metal content.

The following article is organized according to basic complex types, where the preparation, structures, and properties of these complexes are described in some detail. Examples of other types of complexes derived from these most basic examples are discussed. Early reviews of the organometallic chemistry of ruthenium can be found in the comprehensive treatise by Seddon and Seddon,<sup>2</sup> and in the articles by Bruce, Bennett, and Matheson in *Comprehensive Organometallic Chemistry I*;<sup>3</sup> the latter have been updated.<sup>4</sup> A review of the ‘Tentacular Chemistry of [Cp\*Ru(OMe)]<sub>2</sub>’ has also been published.<sup>5</sup>

## 2 CARBONYLS

### 2.1 General Characteristics

For a metal with eight valence electrons, ‘electron precise’ carbonyl structures (*see Electron Precise Compound*) are  $M(CO)_5$  and  $[M(CO)_4]_3$ , which are known for all three metals of the iron group, albeit with quite different properties for the different metals. The next member,  $[M(CO)_3]_6$ , is not formed since a four-connected vertex requires more metal–metal bonding orbitals than can be arranged on the surface of a sphere. Bonding orbitals directed towards the inside of the cluster, however, form MOs that will accommodate more electrons than would be predicted by an 18 valence electron count for each metal (*see Eighteen Electron Compounds*), that is, 86 instead of 84 for a six-vertex *closo* cluster (*see Closo Cluster*). This situation is realized in the iron group by the anions  $[M_6(CO)_{18}]^{2-}$ ,  $M = Fe, Ru, Os$  (isoelectronic to  $M_6(CO)_{16}$ ,  $M = Co, Rh, Ir$ ).

An even-electron fragment, such as  $M(CO)_n$  ( $M = Fe, Ru, Os$ ), can form a three-connected vertex by incorporation of a one-electron ligand, such as hydrogen. Thus, the analog to the tetracarbonyls of the cobalt group  $[M(CO)_3]_4$  in the iron group is represented by the  $MH(CO)_3$  moiety, as in  $[HRu(CO)_3]_4$ , or as in the equivalence of two H or one  $H^-$  for one CO, giving  $H_2Ru_4(CO)_{13}$  or  $[HRu_3(CO)_{11}]^-$ . The equivalence of one CO to two electrons generates species such as  $M(CO)_4^{2-}$  or  $[M_6(CO)_{18-n}]^{2(n+1)-}$  with  $n = 0, 1$ , and  $2$ .

The most stable carbonyl for ruthenium is the trimeric tetracarbonyl  $Ru_3(CO)_{12}$  (**1**), with  $Ru(CO)_5$  (**2**) and  $Ru_2(CO)_9$  (**3**) being much less stable. Compounds (**2**) and (**3**) are prepared from  $Ru_3(CO)_{12}$  and revert to it on standing or irradiation. No neutral homoleptic (*see Homoleptic Compound*) ruthenium carbonyl of higher nuclearity, in particular no analog of  $Os_6(CO)_{18}$ , is known.

Known carbonyl hydrides of ruthenium include the unstable  $HRu(CO)_4$ , as well as the trinuclear  $H_2Ru_3(CO)_{11}$ , tetranuclear  $H_2Ru_4(CO)_{13}$  and  $H_4Ru_4(CO)_{12}$ , and complexes of even higher nuclearity, as well as substitution and deprotonation derivatives. A special feature of ruthenium carbonyl chemistry is the existence of series of carbonyl

halides of varying stability; many mono- and dinuclear carbonyl halides are known.

#### 2.1.1 $Ru_3(CO)_{12}$

As stated above, the one stable binary carbonyl of ruthenium is  $Ru_3(CO)_{12}$  (**1**). This is readily formed from halides or coordination compounds of  $Ru^{III}$  by carbonylation at elevated temperature and pressure.<sup>6–8</sup> This commercially available carbonyl complex is an air-stable orange solid that is soluble in most organic solvents. Its structure consists, like the osmium analog but unlike  $Fe_3(CO)_{12}$ , of a regular  $Ru-Ru-Ru$  triangle with only terminal CO groups. Each  $Ru(CO)_4$  corner is composed of two equatorial and two axial CO groups, with clearly different bonding parameters. Equatorial groups have shorter  $Ru-C$  bonds as well as  $C\equiv O$  bond distances in comparison to the axial CO groups, a difference that can be traced to a ‘ $\pi$ -competition effect’, that is, less back bonding (*see Back Bonding*) for the *trans* axial CO groups, which compete for metal electrons, whereas equatorial CO groups *trans* to a  $Ru-Ru$  bond can make full use of ruthenium d-electrons for back bonding.

Despite the absence of bridging CO ligands, exchange of axial and equatorial CO groups is rapid on the NMR timescale, giving rise to a single  $^{13}C$  signal down to  $-100^\circ C$ . It is found that when either two axial or equatorial positions are occupied by a donor ligand, CO exchange involving these positions is considerably slower. Thus, the pyrazine derivative depicted in Scheme 1 exhibits three bridging carbonyls; a low-temperature process occurs at  $-150$  to  $-90^\circ C$  that affects bridging and equatorial CO groups only, and can be separated from the complete scrambling of all carbonyls at higher temperature. This process, designated as a ‘merry-go-round’ mechanism of

### Scheme 1

CO interchange, can alternatively be viewed as the stepwise movement of the metal core (with the axial groups) by  $60^\circ$ .

### 2.1.2 $Ru(CO)_5$

$\text{Ru}(\text{CO})_5$  (**2**) was first unambiguously characterized by Calderazzo in 1967.<sup>9</sup> The compound was obtained by carbonylating  $\text{Ru}(\text{acac})_3$  in heptane using a  $\text{H}_2/\text{CO}$  mixture. The ensuing heptane solution showed IR absorptions at 2035 and  $1999\text{ cm}^{-1}$  from the newly formed pentacarbonyl. On standing, in particular under the action of light, (**2**) reverts to (**1**) with loss of CO, as can be readily monitored with IR spectroscopy (*see Infrared Spectroscopy*).  $\text{Ru}(\text{CO})_5$  can be prepared as a pure liquid (mp  $-17^\circ\text{C}$ ) by high-pressure carbonylation of (**1**), but the initially colorless liquid rapidly turns yellow on standing owing to the reformation of (**1**).

The  $\text{Ru}_3(\text{CO})_{12}/\text{Ru}(\text{CO})_5$  equilibrium (equation 1) has been much investigated, and the thermodynamic parameters are presented in Scheme 2.<sup>10</sup> Establishment of the equilibrium is accelerated considerably by using a 2% admixture of  $\text{H}_2$  to the CO. The reaction may proceed through one or more carbonyl hydride intermediates (Section 2.1.4). The value of the equilibrium constant suggests that **(2)** is stable at room temperature towards conversion into **(1)** under a few bar of CO. Substitution reactions of **(2)** proceed at or slightly above ambient temperature.  $^{13}\text{C}$  NMR chemical shifts as well as  $\nu_{\text{CO}}$  stretching frequencies in  $\text{M}(\text{CO})_5$  along the series iron, ruthenium, osmium suggest that backbonding from the metal decreases; this correlates with the lower thermal stability of the heavier pentacarbonyls.

$$K = \frac{[\text{Ru}(\text{CO})_5]^3}{[\text{Ru}_3(\text{CO})_{12}][\text{CO}]^3} = 36.6 \text{ at } 100^\circ\text{C}; 13.0 \text{ at } 175^\circ\text{C}$$

$$\Delta G^R = 5.12 \text{ kJ mol}^{-1} (25^\circ \text{C})$$

### Scheme 2

### 2.1.3 $Ru_2(CO)_9$

The ruthenium analog **(3)** of  $\text{Fe}_2(\text{CO})_9$  is obtained as an elusive species through low-temperature UV irradiation of **(2)** in heptane. It loses CO much more readily than **(2)**, converting into **(1)** at ambient temperature. Spectroscopic data have been obtained only in mixtures with **(1)**, but the presence of a single absorption at  $1814\text{ cm}^{-1}$  for bridging CO, along with bands at  $2077$  and  $2018\text{ cm}^{-1}$  for terminal CO, is in accord with a structure similar to the osmium analog with one bridging and eight terminal CO groups. The more stable anion  $[\text{Ru}_2(\text{CO})_8]^{2-}$  (**4**) has been prepared from treatment of **(1)** with  $\text{Na}_2[\text{Ru}(\text{CO})_4]$ ; its structure is unique for complexes of this composition. Whereas the iron and osmium analogs show the expected one axial/three equatorial  $D_{2d}$  arrangement of CO groups, the structure of the ruthenium anion has only  $C_s$  molecular symmetry; the Ru–Ru vector occupies one equatorial position of a trigonal bipyramid (*see Trigonal Bipyramidal*) and one axial ligand of a square pyramid (*see Square Pyramidal*).<sup>11</sup>

(4)

#### 2.1.4 Carbonyl Hydrides and Cluster Carbonylate Anions<sup>12,13</sup>

*Mono- and Dinuclear Compounds.* The pentacarbonyl is a starting material for mononuclear ruthenium carbonyl complexes. As outlined in Scheme 3, reduction with sodium in liquid ammonia yields a pale-colored anion solution (**5**),

### Scheme 3

from which the unstable *cis*-dihydride  $\text{H}_2\text{Ru}(\text{CO})_4$  is obtained by acidification with  $\text{H}_3\text{PO}_4$ . With haloforms, the dihydride converts to the same carbonyl halides (**6**) (Scheme 3) as are obtained from (**2**) with halogen or other halogenation reactions starting from (**1**) (Section 2.1.5).

**Trinuclear Compounds.** A versatile and much-studied compound is the hydrido ruthenium carbonyl anion  $[\text{HRu}_3(\text{CO})_{11}]^-$  (**7**), which is best obtained by treatment of (**1**) with  $\text{NaBH}_4$  in THF and isolated as the  $\text{Me}_4\text{N}^+$  salt.<sup>14</sup> Compound (**7**) has a bridging hydride and a bridging CO across the same edge of the  $\text{Ru}_3(\text{CO})_{10}$  triangle, which is shorter than the other two. The general trend for bridged metal–metal bond lengths is a shortening by CO bridges and widening by H bridges, where the former obviously has the larger effect in cases where they compete.

Reprotonation of (**7**) with strong acid occurs first at the bridging CO to give an elusive  $\mu\text{-C-OH}$  intermediate that rearranges to the neutral dihydride (**8**) (Scheme 4). This is much less stable than the monoanion and decomposes at ambient temperature to (**1**) and the tetranuclear hydrides  $\text{H}_2\text{Ru}_4(\text{CO})_{13}$  (**9**) and  $\text{H}_4\text{Ru}_4(\text{CO})_{12}$  (**10**).

Tetrahedrane (**11**) is the ruthenium analog of the much-studied tricobaltnonacarbonyl clusters  $\text{Co}_3(\text{CO})_9\text{CR}$  (see **Cobalt: Organometallic Chemistry**). The substitution chemistry of (**11**) has been studied.<sup>15</sup> A starting material is prepared from (**11**) by reaction with  $\text{BX}_3$  (equation 2), which gives the chloro and bromo compounds (**12**). In addition, (**11**) can also be treated directly with compounds such as diynes to yield interesting substitution products. For example, when (**11**) is refluxed in THF with diphenylbutadiyne, *cis*- and *trans*-alkene isomers of two alkyne insertion regioisomers are formed (equation 3).<sup>16</sup> The product seems to arise from dehydrogenation of one end of the diyne to yield *cis* and *trans* enynes and an unsaturated monohydride cluster intermediate, which then reacts with the enynes to yield the allylic derivative products

(**12**) and (**13**).

The cluster anion (**7**) has been invoked as an intermediate in the water gas shift reaction (see *Water Gas Reaction*) catalyzed by (**1**).<sup>17,18</sup> In the cycle represented by equations (4–6), (**7**) is formed from (**1**) and hydroxide by a reaction that can be

Scheme 4

the relationships between these high-nuclearity ruthenium hydrido carbonyl clusters have been explored.<sup>22</sup>

The clusters **(18)**, **(19)**, **(20)**, and  $[\text{H}_2\text{Ru}_8(\text{CO})_{21}]^{2-}$  **(21)** are all products from reacting  $\text{Ru}_3(\text{CO})_{12}$  under different conditions. **(18)**, the major product in the synthesis of all of these complexes, has an octahedral core of ruthenium atoms, with an interstitial hydride. The hydride seems to have some stabilizing effect on the octahedral complex, since all products of higher nuclearity are based on this octahedral framework. As seen in Scheme 6, the structure of the octaruthenium dihydride complex **(21)** resembles an octahedron with an additional  $\text{Ru}_7$  unit. Another  $\text{Ru}_7$  unit is added to this complex

### 2.1.5 Halocarbonyl Complexes of Ruthenium

Carbonyl halides of Ru<sup>II</sup> are readily obtained, are stable for all halides, and thus lend themselves as valuable starting materials for the preparation of other ruthenium complexes, in particular those containing  $\sigma$ -donating ligands. The fluoride derivatives are the most outstanding, as there are few examples of fluorocarbonyl complexes in general. Carbonylation of tetrameric RuF<sub>5</sub> or fluorination of (1) with XeF<sub>2</sub> in Freon (CClF<sub>2</sub>CCl<sub>2</sub>F) affords the tetrameric complex [Ru(CO)<sub>3</sub>F<sub>2</sub>]<sub>4</sub> (22). It resembles that of [RuF<sub>5</sub>]<sub>4</sub>, in which three fluorine atoms at each ruthenium are replaced by CO. Use of a larger excess of XeF<sub>2</sub> in the fluorination of (1) gives the monomeric, paramagnetic Ru<sup>III</sup> fluorocarbonyl Ru(CO)<sub>3</sub>F<sub>3</sub> (23). Solid-state susceptibility measurements are in accord with one unpaired electron in a low-spin, d<sup>5</sup> configuration.<sup>23</sup>

### Scheme 6

The main types of halocarbonyl compounds found with the heavier halogens are depicted in Scheme 7. One example has already been presented in Scheme 3. Though methods of preparation other than those shown in Scheme 7 are also successful, reduction with formic acid/hydrohalic acid<sup>24</sup> gives a clear picture of the successive events leading to individual members of the series. Not all compounds listed for chlorine in Scheme 7 can be obtained for bromide and iodine, and in some cases stereoisomers are found with iodine only (cis/trans for  $\text{Ru}(\text{CO})_4\text{I}_2$ ).

Tetracarbonyl compounds  $\text{Ru}(\text{CO})_4\text{X}_2$  (**6**) (Scheme 3) have a *cis*-octahedral structure, established through an X-ray structure determination of the iodide. The second well-established group of halocarbonyls is dimeric tricarbonyls  $[\text{Ru}(\text{CO})_3\text{X}(\mu\text{-X})]_2$  (cf. (**24**) in Scheme 7) with  $C_{2h}$  symmetry, as determined by X-ray crystallography (see *X-ray Crystallography*). Owing to its easy cleavage with even weak donor ligands (e.g. THF) and substitution to  $\text{Ru}(\text{CO})_2\text{L}_2\text{X}_2$ , it is a useful starting material for ruthenium carbonyl chemistry. Treatment of (**6**) with an assortment of bidentate ligands has allowed the synthesis of a variety of carbonyl complexes, including  $\text{Ru}(\text{tmbpy})(\text{CO})_2\text{Cl}_2$  (**25**) and  $[\text{Ru}(\text{dmbpy})(\text{CO})_2\text{Cl}]_2$  (**26**). These substituted bipyridine ligands allow for control over the electronic and steric

properties of the complex, and the monomeric complexes have been shown to be effective precursors for water gas shift and  $\text{CO}_2$  reduction catalysts.<sup>25</sup>

#### 2.1.6 Carbido and Nitrido Clusters<sup>13,26</sup>

Several carbido clusters featuring a  $\text{Ru}_5\text{C}$  or  $\text{Ru}_6\text{C}$  core have been described and structurally characterized (see *Cluster Compounds: Inorganometallic Compounds*

Scheme 7

**Containing Transition Metal & Main Group Elements).** Pyrolysis of (1) in arene solvents gives the carbido carbonyl  $\text{Ru}_6\text{C}(\text{CO})_{17}$  (27) together with  $\text{Ru}_6\text{C}(\text{CO})_{14}(\eta^6\text{-arene})$  in low yields (Scheme 8). Carbido clusters are also formed by heating (1) with  $\text{NaMn}(\text{CO})_5$  in refluxing diglyme. Under milder conditions, this reaction has furnished  $[\text{Ru}_6(\text{CO})_{18}]^{2-}$  (28). A brown suspension formed in an early stage of the reaction is believed to be this dianion, which then, on prolonged heating, is converted into red, soluble  $[\text{Ru}_6\text{C}(\text{CO})_{16}]^{2-}$  (29). At higher CO pressure, (27) is carbonylated to the pentaruthenium carbido carbonyl  $\text{Ru}_5\text{C}(\text{CO})_{15}$  (30) with formation of (2). Under argon pressure this reaction is reversible. Compound (30) is hydrogenated to a dihydride (31) or adds HX to give a halo carbido carbonyl (32).

Scheme 8

$\text{Ru}_5\text{C}(\text{CO})_{15}$  (30) is a regular square pyramid with all CO groups terminal and has basically the same structure as the iron and osmium analogs. Interestingly, the nonparallel edges of the pyramid are at a minimum length in the ruthenium (2.3 Å) as compared to the iron (2.62 Å) and the osmium (2.85 Å) congeners. The carbon atom protrudes out of the basal  $\text{Ru}_4$  plane by 0.11 Å (equation 10).

Homoleptic hepta-, octa-, and nonaruthenium carbido clusters remain unknown. Two structurally similar decaruthenium clusters  $[\text{Ru}_{10}\text{C}(\text{CO})_{24}]^{2-}$  and  $[\text{HRu}_{10}\text{C}(\text{CO})_{24}]^-$  (33) were synthesized by treatment of (1) with mesitylene.<sup>27</sup> They are isostructural with the osmium analogs. The dicarbido cluster,  $[\text{Ru}_{10}(\text{C})_2(\text{CO})_{24}]^{2-}$  (34), was formed by thermolysis of  $[\text{Ru}_6(\text{CO})_{18}]^{2-}$  in refluxing diglyme.<sup>28</sup> Synthesis of (34) was also accomplished by treatment of (1) with an excess of  $\text{CaC}_2$ .

It is formed by the unusual cleavage of the  $C_2^{2-}$  dianion of  $CaC_2$ . The core of (34) consists of two octahedra that share one edge and each have an interstitial carbido atom.<sup>29</sup>

Nitrido clusters are known with a  $Ru_4N$ ,  $Ru_5N$ , or  $Ru_6N$  core. As shown in Scheme 9, treatment of (1) with the PPN azide (PPN[ $N_3$ ]) in THF, followed by evaporation of THF and redissolution in ether, the red complex  $[Ru_4(NCO)(CO)_{13}]^-$  (35) is produced. One CO in (35) is easily displaced by  $H_2$  giving  $[H_2Ru_4(NCO)(CO)_{12}]^-$  (36), isolated as the PPN salt. Protonation of the latter gives neutral trihydride  $H_3Ru_4(NCO)(CO)_{12}$  (37) and some nitrogen-free (hydrido)carbonyl by-products. Refluxing (35) in THF converts it to the nitride cluster anion  $[Ru_4N(CO)_{12}]^-$

(38), which in turn can be protonated to the neutral hydride (39). The hexaruthenium nitride complex  $[Ru_6N(CO)_{16}]^-$  (40) is obtained directly from (1) and PPN[ $N_3$ ] in refluxing THF. Carbonylation under slight pressure (20 bar CO) cleaves (40) into (1) and the pentaruthenium nitrido anion  $[Ru_5N(CO)_{14}]^-$  (41). Treatment of (40) with (1) yields the decaruthenium complex  $[Ru_{10}N(CO)_{24}]^-$  (42) as shown in Scheme 9.

For nitrido clusters, open butterfly structures with a  $Ru_4$  core are observed in (38) and the precursor molecules (35) or (37), where one nitride or isocyanate ligand bridges the open wings of the butterfly.  $Ru_5N$  cores, exemplified by  $[Ru_5N(CO)_{14}]^-$  (41), are of a similar square pyramidal arrangement as  $Ru_5C$  clusters. The nitrido atom in the former is displaced out of the basal plane by as much as 0.21 Å (i.e. about twice as much as the carbon atom in (30)) making the transition to a distorted octahedron. The decanuclear complex (42) exists as a tetracapped octahedron, which is almost indistinguishable from the formally isoelectronic complex  $[Ru_{10}HC(CO)_{24}]^-$ . The hexaruthenium complex (40) has not yet been structurally characterized.

## 2.2 Substitution at Ruthenium Carbonyls

### 2.2.1 Derivatives of $Ru(CO)_5$

As previously mentioned, monosubstitution of  $Ru(CO)_5$  (2) is thermally facile, and a range of the usual L-donor ligand substituted products  $Ru(CO)_{5-n}L_n$  ( $n = 1, 2$ ) is prepared in this way. If L is a phosphine, it occupies an axial position of the trigonal bipyramid (see *Trigonal Bipyramidal*) (with

Scheme 9

exceptions found in chelating ligands). The preparation of  $\text{Ru}(\text{CO})_4\text{PPh}_3$  (**43**) and  $\text{Ru}(\text{CO})_3(\text{PPh}_3)_2$  (**44**) from (**2**) is shown in Scheme 10 as an example of one of the early studies of its reactivity.<sup>30</sup> Thermal substitution led to the bisphosphine derivative from which the dihydride was obtained under forcing conditions.

A route to phosphine- and similarly substituted derivatives that avoids the use of ruthenium carbonyl is performed by the direct reaction of hydrated  $\text{RuCl}_3$  with  $\text{PPh}_3$  in alcoholic solution in the presence of a source of CO. This general method consists of the reductive ligation (see *Reductive Ligation*) of

the metal in the presence of ligand, notably  $\text{PPh}_3$ . The extent of reduction, to  $\text{Ru}^{\text{II}}$  or  $\text{Ru}^0$  in this case, as well as the ligand set around the metal, depends on the particular conditions. The three complexes  $\text{RuHCl}(\text{CO})(\text{PPh}_3)_3$  (**45**),  $\text{RuH}_2(\text{CO})(\text{PPh}_3)_3$  (**46**), and  $\text{Ru}(\text{CO})_3(\text{PPh}_3)_2$  (**44**) (Scheme 11) are all obtained by the same basic procedure, with differences in alkali presence and reaction duration.  $\text{Ru}(\text{CO})_3(\text{PPh}_3)_2$  (**44**) and  $\text{RuH}_2(\text{CO})(\text{PPh}_3)_3$  (**46**) are active hydroformylation (see *Hydroformylation*) catalysts.<sup>31</sup>

Trisubstituted pentacoordinated complexes with phosphine ligands can be synthesized by reduction of  $\text{RuCl}_2(\text{CO})_2\text{L}_2$  (**47**) with magnesium in the presence of L, where  $\text{L} = \text{PPh}_3$  (**48**),  $\text{PMePh}_2$ ,  $\text{PEt}_3$ , or  $\text{P}^i\text{Pr}_2\text{Me}$  (equation 11). The presence of  $\text{L}'$  ( $\text{L}' = \text{PPh}_3$ ,  $\text{P}(2\text{-furyl})_3$ , or  $\text{AsPh}_3$ ) in the magnesium reduction allows for the synthesis of mixed phosphine derivatives, such as the synthesis of (**50**) from (**49**) in equation (12).<sup>32</sup>

Another method for isolating complexes of the type  $\text{Ru}(\text{CO})_2\text{L}_3$  starts with the (hydrido)carbonyl halide complex (**50**). It can be dehalogenated by  $\text{Ag}^+$  in the presence of a stabilizing intermediate ligand (e.g., acetonitrile). The cationic acetonitrile complex (**51**) substitutes easily to give the trisphosphine complex (**52**). Deprotonation of the latter with methoxide gives the neutral *trans*-dicarbonyltrisphosphine (**47**). One of the equatorial phosphine ligands is labile and exchanges with a variety of other ligands to form complexes (**53**), as indicated in Scheme 12. Of particular interest is the dioxygen adduct (**53**) ( $\text{L} = \text{O}_2$ ), formed by exposure to

Scheme 10

Scheme 11

Scheme 12

oxygen. It can function as an oxygen transfer agent or as a catalyst in oxygenation reactions.

### 2.2.2 Derivatives of $\text{Ru(CO)}_4\text{X}_2$

A second large class of mononuclear ruthenium complexes is those formally derived from  $\text{Ru(CO)}_4\text{X}_2$ , that is, six-coordinated  $\text{Ru}^{\text{II}}$ . The synthesis often involves cleavage of carbonyl halide complexes or carbonyl phosphine halide complexes, which are directly obtained from  $\text{RuCl}_3$  with a potential reducing agent and a CO donor, such as formic acid, in the presence of phosphine. The variation of ligands accommodated at a ruthenium center in these complexes is enormous, and is a characteristic of the general stability of octahedral low-spin  $d^6$  complexes of the heavier transition metals. The high ligand field stabilization of  $\text{Ru}^{\text{II}}$  enables combinations of such  $\pi$ -acceptor ligands together with even the hardest  $\sigma$ -donors, such as carbonate, sulfate, or nitrate.<sup>4</sup>  $\text{Ru}^{\text{II}}$  carbonyl and phosphine complexes are known with myriad coligand combinations, having O (oxoanions mentioned, carboxylates, quinones), N (amines, amides, hydrazines, hydrazides, triazenes, formamidates, ureas), or

S (thiocarbonyls,  $\text{CS}_2$ , thio- and dithiocarbonates, carbamates, thiophosphinates, thiophosphates) binding functionalities.

### 2.2.3 Derivatives of $\text{Ru}_2(\text{CO})_9$

Although the parent carbonyl  $\text{Ru}_2(\text{CO})_9$  is virtually unknown, a number of complexes derived by substituting various CO groups of the dinuclear unit for one- or two-electron ligands are of interest owing to some unique transformations they exhibit. The syntheses of these materials begin with (1), which is cleaved by the appropriate ligands or reagents.

By treating (1) with hydrides  $\text{HE}^{\text{IV}}\text{R}_3$  ( $\text{E}^{\text{IV}} = \text{Si, Ge, Sn, Pb}$ ), Knox obtained the  $\sigma\text{-E}^{\text{IV}}\text{R}_3$  derivatives  $\text{Ru(CO)}_4(\text{E}^{\text{IV}}\text{R}_3)_2$  and  $[\text{Ru(CO)}_4(\text{E}^{\text{IV}}\text{R}_3)]_2$ ,<sup>33</sup> the latter with a long unbridged Ru–Ru single bond, formally analogous to  $\text{Mn}_2(\text{CO})_{10}$  (see *Manganese: Organometallic Chemistry*), and with some similarities in their reactivity pattern owing to the ready cleavage of the metal–metal bond in both complexes. Reactions were studied with cycloalkenes and are partly outlined in Section 3.3.

A system lacking  $\pi$ -ligands is obtained by cleavage of (1) with certain bisphosphines  $\text{R}_2\text{P-E-PR}_2$ , which lead to

complexes  $\text{Ru}_2(\text{CO})_4(\mu\text{-CO})(\mu\text{-R}_2\text{P-E-PR}_2)_2$  (**54**). These are formally related to  $\text{Ru}_2(\text{CO})_9$ , in that four carbonyl groups are replaced by two bridging phosphines. A Ru–Ru bond is required to adjust the metal to the 18 valence electron rule (see *Eighteen Electron Compounds*), but this can be readily opened and closed in the course of substitution reactions when the so-called ‘A-frame’ is tightly held together by bridging phosphines. Moreover, the bridging carbonyl group is easily displaced to generate coordinatively unsaturated ruthenium centers, such as its replacement by hydrogen to give (**55**) (Scheme 13).<sup>34</sup> An intriguing case is provided if  $\text{Ag}^+$  oxidation of (**54**) is followed by deprotonation. The resulting alkoxo (hydroxo) complex (**56**) rearranges by CO insertion to an  $\eta^2$ -formate or formic acid complex (**57**). This latter can be deprotonated to yield a complex with a  $\mu_2 - \eta^2\text{-CO}_2$  bonding arrangement (**58**), an unusual bonding situation for  $\text{CO}_2$  (Scheme 13).<sup>35</sup>

The reactions of an analogous A-frame type complex  $[\text{Ru}_2(\text{CO})_4(\mu\text{-dppm})_2(\mu\text{-O}_2\text{CMe})]^+$  (**59**) have been studied extensively and are outlined in Scheme 14. When (**59**) is treated with  $[\text{Et}_3\text{O}][\text{BF}_4]$  in MeCN, the dication (**60**) is formed, which readily converts to (**61**). Reaction of (**61**) with excess of an anion yields coordinatively unsaturated complexes instead of the expected substitution products  $[\text{Ru}_2(\mu\text{-CO})_2(\mu\text{-dppm})_2\text{X}_4]^{2-}$ . The bond between the ruthenium centers is single, while the Ru–X bonds are multiple, probably double, as indicated by bond distances and angles in the crystal structure.<sup>36</sup> An interesting rearrangement occurs when (**59**) is treated with a bidentate ligand such as acetate, bpy, acac, or

8-quinolate (quin). The product is a complex with bridging carbonyls, where the new ligand binds in a bidentate fashion to only one of the ruthenium atoms and the acetate ligand migrates to the opposite ruthenium (**62**). When a second equivalent of the bidentate ligand is added, the acetate is replaced to form (**63**).<sup>37</sup>

#### 2.2.4 Derivatives of $\text{Ru}_3(\text{CO})_{12}$

Substitution at (**1**) has been investigated extensively from a preparative as well as a mechanistic point of view, and most common substitution techniques, including photochemical activation and electron-transfer catalysis, have been employed. Simple thermal substitution leads to a mixture of products, but with special methods, up to 6 of the 12 CO ligands can be replaced without cleaving the trinuclear unit.

Numerous studies of photochemical substitution at (**1**) have been performed.<sup>38</sup> As observed for other polynuclear carbonyls, the photochemistry (see *Photochemistry*) of (**1**) is wavelength dependent. Irradiation at longer wavelength (close to the absorption maximum at 392 nm) presumably gives metal–metal bond cleavage as the primary photoevent, whereas short-wavelength irradiation around 300 nm effects clean CO substitution. At the longer wavelength there is mostly photofragmentation into mononuclear species, whereas at the shorter wavelength if any net change is observed then cluster substitution prevails. Photolysis of (**1**) at 405 nm under 1 atm CO, for example, quantitatively gives (**2**) with a solvent-dependent quantum yield of  $0.028 \text{ mol einstein}^{-1}$  in isooctane

Scheme 13

Scheme 14

(equation 13).

The synthesis of triruthenium derivatives via thermal substitution at (1) is complicated by the frequent formation of product mixtures. Thus, on heating (1) with a phosphine, phosphite, or a related Lewis basic ligand (*see Lewis Acids & Bases*), L, the products are either trinuclear tris- or bis-substituted complexes ( $\text{Ru}_3(\text{CO})_9\text{L}_3$  and  $\text{Ru}_3(\text{CO})_{10}\text{L}_2$ ), or mononuclear complexes (mostly  $\text{Ru}(\text{CO})_3\text{L}_2$ ), and often mixtures thereof. It appears that the first substitution

step is the slowest, so the major product tends to be  $\text{Ru}_3(\text{CO})_9\text{L}_3$ . A second problem with thermal substitution is the high temperatures that must be reached for substitution to occur.

A better approach to substitution at **(1)** is the use of catalytic routes. Induction with  $\text{Me}_3\text{NO}$  has proved successful for **(1)** in some cases, but of particular value for a clean reaction with **(1)** was electron-transfer catalyzed substitution using  $\text{Ph}_2\text{CONa}$  in low concentration as a reductive activator. The likely intermediate is the 49-electron species  $[\text{Ru}_3(\text{CO})_{12}]^-$ , which quickly reacts to form  $[\text{Ru}_3(\text{CO})_{11}\text{L}]^-$ . Electron-transfer occurs again to form  $\text{Ru}_3(\text{CO})_{11}\text{L}$  and to regenerate  $[\text{Ru}_3(\text{CO})_{12}]^-$  to repeat the cycle. The same type of reaction cycle can be induced with  $[\text{PPN}]\text{X}$ , where  $\text{X}$  = acetate, cyanide, or halides. The  $[\text{PPN}][\text{Ru}_3(\text{CO})_{12-n}\text{X}]$  ( $n = 1, 2, 3$ ) species is the intermediate, and  $\text{X}$  is displaced by the appropriate ligand to obtain the substitution product.

The degree of substitution is determined by the initial ratio of **(1)** to ligand, and up to three (or in one instance, four) CO groups are replaced straightforwardly. This method can be employed sequentially, allowing for the preparation of mixed-ligand clusters. More forceful conditions must be employed to replace more CO ligands.

As a characteristic feature of **(1)**, carbonyl substitution, even with some phosphines, is often accompanied by E–H, C–H, or even C–C bond cleavage; the substitution products are trinuclear or dinuclear units with bridging –ER groups and bridging hydrogen. Furthermore, CO groups in **(1)** are susceptible to nucleophilic attack by protic agents if a hydride bridge can be formed via a hydrogen shift. Thus, as given in Scheme 15, primary amines either add to a CO to give a formamidoyl bridge, as in **(64)**, or just add across one Ru–Ru bond, substituting two CO groups, as with aniline in **(65)**.<sup>39</sup> The adjacent functionalities NHR and CO are able to bridge a face of the triangle along with the formation of hydride bridges.<sup>40</sup>

Treatment of **(1)** with methylphenylsulfoximine ( $\text{MePhS}(\text{O})\text{NH}$ ) in THF yields the cluster  $(\mu^2\text{-H})\text{Ru}_3(\text{CO})_9[\mu^3\text{-NS}(\text{O})\text{MePh}]$  **(66)**. The product isolated is either enantiomerically pure or a racemic mixture, depending on whether **(1)** was reacted with optically pure or racemic starting material. Reversible carbonylation of **(66)** produces the cluster

$(\mu^2\text{-H})\text{Ru}_3(\text{CO})_9[\mu^2\text{-NS}(\text{O})\text{MePh}]$  **(67)**. Both of these optically active trinuclear clusters have potential as catalysts for enantioselective reactions.<sup>41</sup>

Reaction of **(1)** with  $\alpha,\beta$ -diimines (such as Diazadienes (dad)) (Scheme 16) occurs mostly through the nitrogen atoms with some acceptor character imposed by the diene system. Products of the reaction of **(1)** with dad depend on the substituents on dad and on the reaction conditions. In contrast to the mononuclear complex  $\text{Ru}(\text{CO})_3\text{dad}$  **(68)** and trinuclear  $\text{Ru}_3(\text{CO})_8(\text{dad})$  **(69)**, where dad acts as an eight-electron ligand analogous to the iron congener, the dinuclear complex  $\text{Ru}_2(\text{CO})_6(\text{dad})$  **(70)** is obtained in which dad is coordinated in an unusual  $\sigma/\pi$ -mode through both nitrogens and one carbon, thereby acting as a six-electron ligand.

### 3 ALKENE AND CYCLOALKENE COMPLEXES

#### 3.1 Alkene Complexes of $\text{Ru}^{\text{II}}$

Ruthenium complexes of alkenes, dienes, or cyclodienes in oxidation states 0 and II are known. From a preparative view, an important class of compounds is the oligomeric or polymeric complexes of composition  $[(\text{dialkene})\text{RuX}_2]_n$ , which often serve as reagents for further transformations. Their synthesis is similar to the procedure that has been detailed for phosphine complexes; that is, when  $\text{RuCl}_3(\text{aq})$  is refluxed in alcohol in the presence of the diene, an insoluble brown to orange oligomeric complex is deposited. However, the use of

Scheme 15

Scheme 16

cyclohexadiene produces the oligomer  $[(C_6H_6)RuCl_2]_n$  (see Section 6.3). Because these polymers are formed in high yield directly from commercially available  $RuCl_3$ , this method is one of the best entries into organometallic ruthenium chemistry and is valuable in many cases where reaction of  $Ru_3(CO)_{12}$  leads to product mixtures or is unsuitable for other reasons. The oligomers are cleaved by various donor ligands, L, notably amines or nitriles, to form soluble ionic or molecular monomers, ranging in composition from  $[(diene)RuLX_3]^-$  to  $(diene)RuL_2Cl_2$  and  $[(diene)RuL_4]^{2+}$ .

A soluble dimer  $[Ru(cod)Cl_2]_2$  (**71**), having the same formula as the insoluble polymer, has been isolated as a product from the reductive complexation of cod to ruthenium by Zn in EtOH/THF. The compound has been structurally characterized, and the Ru–Ru distance of 2.791 Å in this compound is in the range found for Ru–Ru single bonds, whereas a double bond would be required to satisfy the effective atomic number rule (see *Effective Atomic Number Rule*).<sup>42</sup>

Refluxing (**71**) in cod and acetonitrile yields the monomeric complex  $[(cod)Ru(CH_3CN)_4]^{2+}$  (**72**), which is useful in

the synthesis of a variety of organometallic complexes owing to facile substitution of the acetonitriles.<sup>43</sup> Through

a different synthetic method, a chloride-bridged diruthenium acetonitrile complex (**73**) is isolated. It was formed by reaction of (cod)Ru(cot) with naphthalene, followed by addition of acetonitrile. Compound (**73**) consists of two Ru<sup>II</sup> centers with octahedral geometries. The complex undergoes two reversible one-electron oxidations, which is in contrast with other dimeric Ru<sup>II</sup> complexes of this type.<sup>44</sup>

Another class of ruthenium alkene complexes contains those derived from the hexaaqua ion [Ru(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup>. The thermodynamically stable complex [(cod)Ru(H<sub>2</sub>O)<sub>4</sub>]<sup>2+</sup> (**74**) forms directly from [Ru(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup> and cod in alcohol at ambient temperature (equation 14). In (**74**), the redox potential of Ru<sup>II</sup> has shifted more positive for the oxidation to Ru<sup>III</sup> and more negative for the reduction to Ru<sup>I</sup> or Ru<sup>0</sup>, so as to impose a high stability towards disproportionation (*see Disproportionation*) (in contrast to the readily disproportionating aqua ion [Ru(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup>). The X-ray crystal structure (*see X-ray Crystallography*) of the Tosylate (Ots)<sup>−</sup> salt disclosed quite different R–OH<sub>2</sub> distances of 2.095(2) and 2.156(2) Å for water *gauche* or *trans* to the alkene double bond, showing the structural *trans* effect (*see Trans Effect*) of the latter on a σ- (and π-) donor ligand *trans* to it.<sup>45</sup>

### 3.2 Alkene Complexes of Ru<sup>0</sup>

Mononuclear carbonyl alkene complexes of Ru<sup>0</sup> exhibit moderate to low stability. The same is true for carbonyl phosphine complexes with unsubstituted alkenes, such as Ru(CO)<sub>2</sub>(PPh<sub>3</sub>)<sub>2</sub>(C<sub>2</sub>H<sub>4</sub>). An entry into the substitution chemistry of carbonyl alkene complexes is the thermal preparation of (cod)Ru(CO)<sub>3</sub> by refluxing (**1**) and cod in benzene. Isolation of the pure product requires double chromatography of a nearly colorless material of low-melting point and gives the product in about 60% yield.<sup>46</sup> Facile exchange of the cod ligand for conjugated dienes occurs in high yield.

A versatile reductive complexation method that leads directly to cycloalkene Ru<sup>0</sup> complexes consists of treatment of RuCl<sub>3</sub> with activated Zn in ethanol or methanol (or mixtures with THF) in the presence of an alkene (Scheme 17).<sup>47,48</sup> Starting from a diene, a dehydrogenation is required to provide the metal with 18 valence electrons (*see Eighteen Electron Compounds*), and this is accomplished by hydrogenating one of the cycloalkenes to a monoalkene, which as the weakest ligand is replaced by another diene. An extension of this

method was found by prolonged refluxing of RuCl<sub>3</sub> in ethanol in the presence of Cyclooctatetraene (cot). The product was the insoluble oligomer [(C<sub>8</sub>H<sub>10</sub>)RuCl<sub>2</sub>]<sub>n</sub>, where the cot ligand was hydrogenated to form cyclooctatriene. The same procedure also gives the analogous cycloheptatriene complexes.

### 3.3 Diene and Cyclodiene Complexes Derived from Ru<sub>3</sub>(CO)<sub>12</sub>

Simple alkene complexes, where one alkenic group replaces a carbonyl in (**1**) or (**2**) are unstable, as already stated, and have been characterized only in solution. For example, the monoethylene complex Ru(CO)<sub>4</sub>(η-C<sub>2</sub>H<sub>4</sub>) can be made photochemically in solution by irradiating (**1**) or (**2**) in the presence of an excess of ethylene. This compound decomposes below room temperature but its stability is enhanced in the presence of excess CO; presumably CO dissociation is the initial step of the decomposition. The compound serves as an intermediate for the preparation of more stable alkene complexes from electron-deficient alkenes by simple exchange at low temperature in solution. Ru(CO)<sub>4</sub>(η-alkene) complexes with electrophilic alkenes can also be isolated from Ru(CO)<sub>4</sub>(η-C<sub>2</sub>H<sub>4</sub>) in this way.

A number of mono-, di-, and trinuclear carbonyl cycloalkene complexes derived from (**1**) have been prepared and studied, some in considerable detail owing to interesting modes of fluxionality of the cyclopolyene ligand. Reaction of Ru<sub>3</sub>(CO)<sub>12</sub> with cycloalkenes gives products in which the triangle of ruthenium atoms is preserved and those in which it is cleaved into mono- and dinuclear units (e.g., (**75**) in equation 15). Products can also form by increasing the number of metal centers, such as the reaction of Ru<sub>3</sub>(CO)<sub>12</sub> with C<sub>8</sub>H<sub>14</sub>, which forms the trinuclear cluster [H<sub>2</sub>Ru<sub>3</sub>(CO)<sub>9</sub>(μ<sup>3</sup>-η<sup>2</sup>-C<sub>8</sub>H<sub>12</sub>)] and the hexanuclear carbido-cluster [Ru<sub>6</sub>C(CO)<sub>15</sub>(μ<sup>3</sup>-η<sup>2</sup>-C<sub>8</sub>H<sub>12</sub>)].<sup>49</sup>

Like all complexes of this type, (**75**) is fluxional (*see Fluxional Molecule*) at ambient temperature with respect to the cot ligand. The low-temperature limiting spectrum of (**75**) is in accord with the solid-state structure as inferred from the analogous iron compound that had been determined by X-ray analysis (*see X-ray Crystallography*), showing one allylic and one 'en-ylidic' bound Ru(CO)<sub>3</sub> group with an interposed, noncomplexed double bond. This bonding mode is characteristic for many metal fragments coordinated to cot, cyclooctatriene, or other cyclotrienes.<sup>50</sup>

Scheme 17

Of particular interest is the bis(cot) compound (**76**) formed from reaction of  $\text{Ru}_3(\text{CO})_{12}$  and cot in *n*-octane reflux (equation 16). This molecule is fluxional (*see Fluxional Molecule*) at room temperature and below. A solid-state structure determination<sup>51</sup> established the near  $C_2$  molecular symmetry (a  $C_2$  axis passing through the carbonyl-free ruthenium atom and intersecting the opposite Ru–Ru vector). Only one enantiomer of the chiral molecule was found in the crystal, thus spontaneous resolution had occurred during crystallization (this could be accomplished by interconversion of enantiomers through the interchange of CO groups). One ruthenium atom is complexed only to alkenes, and the Ru–Ru distances to the other two metal atoms are longer than the bond between the two  $\text{Ru}(\text{CO})_2$  groups. Since the alkene is a weaker  $\pi$ -acceptor (*see  $\pi$ -Acid Ligand*) compared to CO, it takes less electron density out of the metal–metal antibonding HOMO.

In addition to hydrogen shifts, ring contraction is observed in reactions of cycloalkenes with ruthenium carbonyl centers containing  $\text{E}^{\text{IV}}$  ligand derivatives  $\text{Ru}(\text{CO})_4(\text{ER}_3)_2$  (**77**) and  $[\text{Ru}(\text{CO})_4\text{ER}_3]_2$ . Heating of either (**77**) or  $[\text{Ru}(\text{CO})_4\text{ER}_3]_2$  with cot gives a mixture of two complexes (**78**) and (**79**) (Scheme 18), the latter in most cases in low yield.<sup>52</sup> In (**78**) one of the substituent groups  $\text{ER}_3$  ( $\text{GeMe}_3$  or  $\text{SiMe}_3$ ) has migrated to the cot ring and is found stereospecifically in the *endo* position. For cot as the ligand, complexation is through an allyl fragment and an isolated double bond as shown in (**78**), leaving one uncomplexed double bond in between,

Scheme 18

whereas for the complex derived from cycloheptatriene (cht), a conjugated dienyly system is formed, as in (**80**).

The second major reaction product from the reaction of cot with (**77**) is the dinuclear complex (**79**) with a coordinated pentalene ligand ( $\text{C}_8\text{H}_6$ ) that is highly unstable as a free hydrocarbon. In (**79**), the pentalene ligand has lost its substituent; however, since the pentalene complex can be generated from (**78**) in somewhat higher yield (about 30%) than in the direct reaction between (**77**)/ $[\text{Ru}(\text{CO})_4\text{ER}_3]_2$  and cot, it seems that (**78**) is an intermediate in the formation of (**79**). The  $\text{ER}_3$  group appears to be a necessary prerequisite for dehydrogenative ring contraction. The exact mechanism of this reaction is not known.

## 4 RUTHENOCENE

### 4.1 General Properties and Preparation

The sandwich complex ruthenocene,  $\text{RuCp}_2$  (**81**), is more stable than its iron analog ferrocene (see *Ferrocene*). With a decomposition temperature around  $600^\circ\text{C}$ , ruthenocene is among the most stable organometallic compounds known. Similarities to ferrocene not only include structural features but also reactivity, such as facile electrophilic substitution at the cyclopentadiene ring. As a substituent, the ruthenocenyl group  $\text{RuCp}(\text{C}_5\text{H}_4)$  (Rc) is slightly less electron releasing than ferrocene ( $\sigma_p - 0.05$  vs.  $-0.10$  for ferrocene), but in direct metal–R interactions ruthenium forms stronger bonds. Thus, protonation of ferrocene with strong acids has yielded spectroscopic evidence for metal protonation at low temperature and rearrangement to a 16 valence electron  $\text{CpFe}^+$  cation, whereas metal-protonated ruthenocenium cations, in particular those derived from penta- and decamethylruthenocene are readily isolated as salts.<sup>53</sup>

The common metathesis reactions for the preparation of metallocenes, treating a metal salt  $\text{MX}_2$  with  $\text{NaCp}$ , are hampered in the case of ruthenium by the lack of suitable  $\text{Ru}^{\text{II}}$  salts. ( $\text{RuI}_2$  is commercially available, but is still not commonly used in the synthesis of ruthenocene.) Thus, ruthenocene has been obtained from  $\text{Ru}(\text{acac})_3$  and  $\text{NaCp}$  in very low yield<sup>1,54,55</sup> and later from  $\text{RuCl}_3$  and  $\text{NaCp}$  in 50–60% yield. It has now become apparent that alkene polymers, in particular  $[\text{Ru}(\text{nbd})\text{Cl}_2]_x$ , but also  $[\text{Ru}(\text{cod})\text{Cl}_2]_x$  and hydrazine derivatives (Section 3.1), can serve as  $\text{Ru}^{\text{II}}$  precursors.<sup>56</sup> Equally successful in many cases is reductive complexation of cyclopentadiene in ethanol in the presence of Zn (Section 3.2), which furnishes the metallocene in about 80% yield. Decamethylruthenocene (**82**) was first obtained by the Zn reduction route in 20% yield,<sup>57</sup> but can now be prepared conveniently from halide complexes  $[\text{Cp}^*\text{RuCl}_2]_2$ <sup>53</sup> or  $[\text{Cp}^*\text{RuCl}]_4$ , a common method for the preparation of symmetrical and unsymmetrical sandwich compounds of ruthenium featuring one alkyl-substituted ligand.

### 4.2 Structure

The molecular and crystal structure of (**81**) is simpler than that of ferrocene as only one polymorph featuring eclipsed conformation of the cyclopentadienyl rings, has been found at ambient and low (100 K) temperature. The larger metal–carbon distance (2.186 Å in (**81**) vs. 2.03 or 2.06 Å in ferrocene) corresponds to the larger metal covalent radius (see *Covalent Radii*) and may also be responsible for the fact that an eclipsed conformation is found for the solid-state structure of decamethylruthenocene (**82**),<sup>56</sup> as opposed to decamethylferrocene where more closely spaced methyl groups impose the staggered  $D_{5d}$  conformation.

### 4.3 Redox Reactions and Bent Metallocenes (see *Bent Metallocenes*): $\text{RuCp}_2\text{X}^+$

Like ferrocene, ruthenocene is stable to reduction, and no anion or controlled reductive cleavage has yet been reported. One of the major differences between ruthenocene and ferrocene is their behavior in oxidation reactions. The facile and reversible one-electron oxidation of ferrocene is used as the principal electrochemical standard in nonaqueous solvents.<sup>58</sup> In contrast, an apparently irreversible two-electron oxidation of ruthenocene occurs under all but the most selective conditions. This behavior, at first sight in disagreement with the tendency of the heavier transition metals to stabilize higher oxidation states, is rationalized by considering the nature of the  $^2\text{E}(\text{d}_{xy})$  ground state of the radical cation (as proved by EPR (see *Electron Paramagnetic Resonance*)) for the cation (**82**)<sup>+</sup>.<sup>57</sup> Since there is increasing ligand character in the degenerate  $\text{d}_{xy}/\text{d}_{x^2-y^2}$  orbital pair with the 4d and 5d transition metals, single occupancy of these levels causes higher chemical reactivity.

For ruthenocene, the subsequent reaction (Scheme 19) is addition of a nucleophile (see *Nucleophile*) to the metal center. Generally, the nucleophile is a halide ( $\text{X}^-$ ), but it can be mercury from a mercury electrode; a second oxidation then gives the cations  $[\text{RuCp}_2\text{X}]^+$  (**83**) or  $[\text{Cp}_2\text{Ru}-\text{Hg}-\text{RuCp}_2]^{2+}$ , respectively. In the absence of a stabilizing nucleophile, disproportionation (see *Disproportionation*) prevails. The halide complexes are isolable, and the iodide and chloride cations  $[\text{RuCp}_2\text{X}]^+$  have been structurally characterized.<sup>59,60</sup> The crystal structure of the bromide analog exists only with permethylated ligands.<sup>61</sup>

Bimolecular exchange between  $[\text{RuCp}_2\text{X}]^+$  and  $\text{RuCp}_2$  occurs as an inner-sphere (see *Inner-sphere Reaction*) electron transfer. The effects of varying the transferred atom (X), counterion, solvent, and substitution on the cyclopentadienyl ligands have been studied. It was found that the exchange rate constant is lowest with chlorine, and increases down the periodic table to iodine. Among complexes with the same halide, exchange rates increase with the number of methyl groups on the cyclopentadienyl ligands. This trend seems to be a consequence of the electronic effects of methylation on reaction energetics and shows that the mechanism is through the bridged transition state (Scheme 20).<sup>62</sup>

A different mode of stabilization for the monocations is dimerization. While the osmocene (see *Osmocene*)

Scheme 19

### Scheme 20

dimer  $[\text{Cp}_2\text{Os}-\text{OsCp}_2]^{2+}$ , formed through one-electron oxidation, has been isolated and structurally characterized, the corresponding ruthenocenium dimer, although not structurally authenticated, has been studied. As indicated with CV experiments, the electrochemical oxidation of (**81**) produces mainly the dimer dication (**84**) in equilibrium with the monocation (**81**)<sup>+</sup> complex, as shown in equation (17). Complex (**84**) and the osmium analog represent the only two unbridged metal–metal bonded metallocenes.<sup>63</sup>

A reversible one-electron oxidation (equation 18) was observed with (**82**) in a nonnucleophilic solvent (such as CH<sub>2</sub>Cl<sub>2</sub>).<sup>57</sup> With rigorous exclusion of even the weakest nucleophiles (e.g., PF<sub>6</sub><sup>−</sup>), using [(3,5-(CF<sub>3</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>)<sub>4</sub>B]<sup>−</sup> as the supporting electrolyte in cyclic voltammetry, a reversible one-electron oxidation of (**81**) is possible as well.<sup>64</sup>

## 4.4 Substitution

As mentioned above, ruthenocene is susceptible to electrophilic substitution in a manner similar to ferrocene. Thus, common reactions for activated aromatics, such as acylation ( $\text{RCOCl}/\text{AlCl}_3$ ), sulfonation ( $\text{SO}_3$  in dioxane), aminomethylation ( $\text{CH}_2(\text{NMe}_2)_2$ ), Vilsmeier–Haack formylation ( $\text{DMF}/\text{POCl}_3$ ), arylation via diazonium salts, as well

as mercuration and lithiation, have been performed with **(81)**.<sup>4,65</sup> The perhalogenated ruthenocene has commonly been obtained from the decaacetoxymercury derivative **(85)**, which is formed as a highly insoluble product from mercuration of **(81)** with  $\text{Hg}(\text{OAc})_2$  in methylene chloride.<sup>66</sup> Halogenation of **(85)** with halogens ( $\text{X}_2$ ) gives the perhaloruthenocenes **(86)** in one step, with yields from 40 to 70% depending on the halide. Repeated lithiation and successive quenching of the metallated ruthenocene with  $\text{C}_2\text{Cl}_4$  to give finally perchlororuthenocene is another method for the synthesis of **(86)** (Scheme 21).

Although monolithiated metallocenes are well known, cyclopentadienyl ligands with higher lithiation are rare. Pentalithiocyclopentadienyl ligands have been isolated from the treatment of (**85**) or  $\text{Cp}^*\text{Ru}[\text{C}_5(\text{HGOAc})_5]$  (**87**) with methylolithium (Scheme 22).  $\text{Ru}(\text{C}_5\text{Li}_5)_2$  and  $\text{Cp}^*\text{Ru}(\text{C}_5\text{Li}_5)$  complexes have been isolated, respectively, with this synthetic route. They can easily be converted to halogenated complexes by treatment with electrophiles such as bromine or methyl iodide.<sup>67</sup> In addition to the lithiation method, ruthenocene complexes with unevenly substituted cyclopentadienyl ligands have been isolated using  $\text{RuCp}(\eta^4\text{-butadiene})\text{Cl}$  (**88**). Refluxing (**88**) with  $\text{Tl}(\text{OC}_6\text{F}_5)$  in THF yields  $\text{RuCp}((2\text{-}6\text{-}\eta^5\text{-C}_6\text{F}_5\text{O}))$ , which is converted to the crystallographically characterized complex  $\text{RuCp}(\eta^5\text{-C}_5\text{F}_5)$  with flash vacuum pyrolysis.<sup>68</sup>

A notable substitution product of ruthenocene is ethynyl-ruthenocene, which can be bound to estradiol, a form of estrogen studied for breast cancer treatment. With the rigid alkyne spacer, the steroid's affinity to the estrogen receptor was surprisingly unchanged upon addition of the metallocene. The addition of organometallic complexes to biomolecules may allow for the selective tuning of properties of the molecule.<sup>69</sup>

Another interesting example of a substituted ruthenocene complex is produced upon the treatment of  $\text{Cp}^*\text{Ru}_2\text{Cl}_4$  with excess Norbornadiene (nbd) in refluxing ethanol. The resulting  $\text{Cp}^*\text{Ru}(\eta^5\text{-C}_5\text{H}_4\text{C}_9\text{H}_{11})$  complex has a cyclopentadienyl ring with a tricyclo[4.2.1.0<sup>2,5</sup>]-non-7-en-3-yl substituent. This unique substituent is a result of nbd coupling, C–C bond cleavage, hydrogen migration, and hydrogen loss. The dimerization or trimerization of norbornadiene is common among transition metal complexes, but the formation of a substituted metallocene from the nbd coupling is unprecedented.<sup>70</sup>

Scheme 21

Scheme 22

#### 4.5 $\alpha$ -Ruthenocenyl Carbonium Ions and $\eta^6$ -Fulvene Complexes

Similar to ferrocene, the ruthenocene derivatives (**89**) substituted with a  $\text{CR}^1\text{R}^2$  group are greatly stabilized in comparison to noncomplexed carbenes or carbonium ions. In fact, from the enhanced barrier to internal rotation in the  $\alpha$ -ruthenocenyl carbonium ion  $\text{Ru-CHMe}^+$  ( $>130 \text{ kJ mol}^{-1}$ ) compared with the related ferrocene derivative ( $70 \text{ kJ mol}^{-1}$ ), even greater stabilization in ruthenocene is expected.

The common preparative route to these cations by protonation induced OH abstraction from an  $\alpha$ -hydroxymethyl group (equation 19) is complemented for methylruthenocenes by the direct and facile deprotonation of a ring methyl group in the cation (equation 20). Thus, oxidation of (**82**) in the presence of a halide ion rapidly converts the initially formed ruthenocenium cation (**82**)<sup>+</sup> into the

respective fulvene, which is oxidized by excess (**82**)<sup>+</sup> to the fulvenyl or  $\alpha$ -methylene cation (**90**). Complex (**90**) can also be obtained directly from (**82**) by hydride abstraction through  $\text{Ph}_3\text{CBF}_4$  in high yield (equation 20).<sup>71</sup> An X-ray structure determination (*see X-ray Crystallography*) of (**90**) showed the existence of one shorter Ru–C bond, a displacement of ruthenium towards this bond, and inward bending of this atom from the otherwise planar  $\text{C}_5\text{Me}_4$  ring.<sup>72</sup> Owing to their easy preparation and facile addition of various nucleophiles, these cationic fulvene complexes can be of high synthetic value. In an attempt to analyze the effect of end groups on charge localization of polymethines, the crystallographically characterized 1,3-(diruthenocenyl)allylium cation was synthesized. It consists of a ( $\eta^6$ -fulvene)( $\eta^5$ -cyclopentadienyl)ruthenium cation bridged by vinylene to a symmetrical ruthenocene. This is a unique molecule in that it is a symmetrically substituted species that adopts an unsymmetrical structure and localizes the charge at

only one end.<sup>73</sup>

#### 4.6 Heteroruthenocenes and Ruthenocene-Related Dienyl Complexes

Among the few known heteroruthenocenes are cationic thiophene- and bis(thiophene)ruthenium, electronic analogs to arene ruthenium sandwich complexes (Section 5), and derivatives featuring a tetramethylpyrrole (tp) ligand,  $\text{Cp}^*\text{Ru}(\text{tp})$  (**91**) and  $\text{Ru}(\text{tp})_2$ ,<sup>74</sup> prepared by an adaptation of the Zn reduction method to the chloro complex  $[\text{Cp}^*\text{RuCl}_2]_2$  (**92**) (equation 21). The methyl groups are necessary to prevent  $\sigma$ -complexation of the pyrrole ligand; however, under suitable conditions ( $[\text{Cp}^*\text{Ru}(\text{acac})]_2/\text{Zn}^{2+}/\text{pyrrole}$  in ether), the preparation of at least  $\text{Cp}^*\text{Ru}(\text{pyrrole})$  (**93**) has been equally successful (equation 22).

A series of so-called ‘half-open ruthenocenes’,<sup>75</sup> notably  $\text{Cp}^*\text{Ru}(\eta^5\text{-C}_5\text{R}_7)$ , are prepared similarly from  $\text{Cp}^*\text{Ru}$  precursor complexes ( $\text{Cp}^*\text{RuCl}$ )<sub>4</sub> or ( $\text{Cp}^*\text{RuOMe}$ )<sub>2</sub> and dienyl alkali

salts or dienes and a mild base to effect dehydrohalogenation. Half-open ruthenocenes are versatile, allowing for incorporation of substituents onto, as well as heteroatoms into, the pentadienyl fragment. X-ray crystallographic studies (*see X-ray Crystallography*) have found that the  $\text{C}_5\text{R}_7$  ligands are essentially planar with rather short Ru–dienyl bond lengths (2.12–2.19 Å). Varying the composition of the pentadienyl ligand allows for adjustments to the chemistry of the complex. For example, oxodienyl complexes are generally more reactive than all-carbon analogs, owing to the weaker coordination of the oxygen.<sup>76</sup>

Open ruthenocenes,  $\text{Ru}(\eta^5\text{-C}_5\text{R}_7)_2$ , with asymmetric substitution of the pentadienyl ligands (*see Pentadienyl Ligand*) allow for the synthesis of diastereomeric products. The treatment of (**1**) with 2-methyl-4-phenylpentadiene and zinc dust yielded bis(2-methyl-4-phenylpentadienyl)ruthenium (**94**). The product consists of a pair of diastereomers, which were easily separated by fractional crystallization because of their substantially different solubilities. One isomer could exist as a pair of enantiomeric rotamers, each with  $C_1$  symmetry (**94a**) and (**94b**), while the other could be a pair of diastereomeric rotamers, both with  $C_2$  symmetry (**94c**) and (**94d**). Both of the former rotamers are observable, but (**94c**) is the only form of the latter, and interconversion to (**94d**) does not occur. The possibility of isomerization with photochemical initiation still remains to be investigated.<sup>77</sup>

The tricarbadeboranyl ligand ( $\text{C}_3\text{B}_7\text{H}_{10}$ ) has been compared with the cyclopentadienyl anion, as both have

the same charge and similar electron-donating ability. However, metal complexes with tricarbadiabecaboranyl exhibit greater oxidative, chemical, thermal, and hydrolytic stability compared to metallocenes. Nonetheless, the cage-slippage of the tricarbadiabecaboranyl ligand between  $\eta^6$  and  $\eta^4$  coordination modes mirrors a similar  $\eta^5$  to  $\eta^3$  slippage in metallocenes. The ruthenocene-like complex *commo*-Ru-(2-Me-*closo*-1,2,3,4-RuC<sub>3</sub>B<sub>7</sub>H<sub>9</sub>)<sub>2</sub> (**95**) was synthesized by treating RuCl<sub>2</sub>(cod)<sub>x</sub> with Li(6-Me-*nido*-5,6,9-C<sub>3</sub>B<sub>7</sub>H<sub>9</sub>) in glyme.<sup>78</sup>

An interesting characteristic of ruthenocene is that it is a photoinitiator for the anionic polymerization of ethyl 2-cyanoacrylate. Solutions with millimolar concentrations of the complex in neat cyanoacrylate polymerize to a hard, plastic solid within seconds upon exposure to light. The low concentration of ruthenocene required for the polymerization makes it desirable in applications such as coating and adhesives that require solvent-free solutions of monomer.<sup>79</sup>

## 5 (ARENE)(CYCLOPENTADIENYL) AND BIS(ARENE) RUTHENIUM COMPLEXES

### 5.1 [Ru(arene)(cyclopentadienyl)]<sup>+</sup> Complexes

This type of sandwich complex, first reported with iron as the central metal, has now become widespread with ruthenium as well. Early routes to ruthenium complexes were modeled on iron chemistry, and used the AlCl<sub>3</sub>-catalyzed exchange of a cyclopentadienyl ligand for an arene in ruthenocene, or reaction of CpRu(CO)<sub>2</sub>Cl with AlCl<sub>3</sub>/arene. These methods are less successful with ruthenium than with iron, however, owing to the greater stability of ruthenocene. A mixture of arene, pentamethylcyclopentadiene, and RuCl<sub>3</sub> in the Zn reduction method gives good yields of the mixed-sandwich cations. A

great variety of [Ru(arene)(cyclopentadienyl)]<sup>+</sup> complexes, including functionally substituted arenes, polyphenyls, and paracyclophanes, phenols, condensed polyaromatics, as well as the six-electron heterocycles thiophene and pyridines, have been complexed to ruthenium.

With the less tightly bound polyarenes or heteroarenes, displacement of the arene has been observed. Thus, sensitive dications with these types of ligands can only be prepared and handled in nonnucleophilic environments. Behavior in the pyridine complexes is particularly interesting. Here a rearrangement from the initially formed  $\pi$ -complex (**96a**) to a  $\sigma$ -complex (**96b**) occurs (equation 23).<sup>80</sup> However, heating of (**96b**) (L = acetonitrile) under vacuum gives (**96a**).<sup>81</sup> It thus appears that the pyridine  $\pi$ -complex is stable in the absence of additional  $\sigma$ -ligands, including excess pyridine.

Recently, organometallic ruthenium chemistry has found its way into biological applications. Treating [Cp<sup>\*</sup>Ru(MeCN)<sub>3</sub>][CF<sub>3</sub>SO<sub>3</sub>] with amino acids in THF yields  $\eta^6$ -coordinated amino acid complexes of the type [Cp<sup>\*</sup>Ru( $\eta^6$ -HaaOH)][CF<sub>3</sub>SO<sub>3</sub>], where HaaOH = L-HPheOH (phenylalanine) or L-HTrpOH (tryptophan), as shown in equation (24). Similarly, dipeptide and cyclopeptide complexes can be synthesized under parallel conditions. These types of complexes are essentially Cp<sup>\*</sup>Ru<sup>II</sup> labeled peptides, which could have a notable impact on the analysis of protein receptor sites.<sup>82</sup>

Ruthenocene derivatives have also been studied as potential second-order nonlinear optical materials. Using the [Cp<sup>\*</sup>Ru]<sup>+</sup> fragment, several aromatic systems have been synthesized and studied for this goal. The [Cp<sup>\*</sup>Ru]<sup>+</sup> fragment was synthesized by treating [Cp<sup>\*</sup>Ru(OMe)]<sub>2</sub> with triflic acid. Various aromatic

complexes were then added to this reaction mixture to form sandwich derivatives of the type shown in equation (25).<sup>83</sup>

## 5.2 Neutral Ru(arene)(cyclopentadienyl) Complexes

An interesting derivative of the pyrrole ring that has found its way into ruthenocene chemistry is *meso*-octaethylporphyrinogen. The tetraanion is of interest because it allows for  $\eta^1$ ,  $\eta^3$ , or  $\eta^5$  binding and can donate from 8 to 24 electrons. It has an internal  $\text{N}_4$  site that easily binds nickel(II). Treatment of the lithiated porphyrinogen with  $\text{Ru}(\text{Cl})(p\text{-cymene})_2(\mu\text{-Cl})_2$  or  $\text{Ru}(\text{Cl})(\text{cod})_2(\mu\text{-Cl})_2$  binds one of the pyrrole rings to the  $\text{Ru}(p\text{-cymene})$  (**97**) and the  $\text{Ru}(\text{cod})$  fragments, respectively. Once the ruthenium is bound, the cod ligand undergoes rearrangement to form an  $\eta^5$ -cyclopentadienyl-like ligand (**98**). With a  $\text{Ni}^{\text{II}}$  and  $\text{Ru}^{\text{II}}$  center, it is an overall neutral molecule.<sup>84</sup>

## 5.3 Bis(arene) Complexes

Bis(arene) complexes of ruthenium (**99**), first prepared in relatively low yield by the Fischer–Hafner synthesis (see *Fischer–Hafner Synthesis*) ( $\text{MCl}_3/\text{AlCl}_3/\text{arene}$ ) are now readily available through solvento cations  $[(\text{arene})\text{RuS}]^{2+}$  ( $\text{S} = \text{acetone, nitromethane}$ ), which in turn are made from the dimeric half-sandwich halides  $[(\text{arene})\text{RuCl}_2]_2$  (Section 6.3) with  $\text{Ag}^+$  with the appropriate arene as solvent (Scheme 23). This method allows a whole range of functionalities to be incorporated to at least one of the arenes. The dications (**99**)<sup>2+</sup> are of relatively high solvolytic stability and are decomposed by DMSO only to form  $[(\text{arene})\text{Ru}(\text{DMSO})_3]^{2+}$ .

Whereas  $[\text{CpRu}(\text{arene})]^+$  cations are not easily reduced electrochemically (with  $[\text{CpRu}(\text{polyarene})]^+$  being an exception), the bis(arene) complexes have aroused interest owing to their two-electron redox change that converts one arene from an  $\eta^6$ - into a bent  $\eta^4$ -ligand. An electrochemical investigation of this process revealed that the second electron transfer is slower than the first one. In neutral  $\text{Ru}(\eta^6\text{-arene})(\eta^4\text{-arene})$  complexes (**99**), the bonding mode between  $\eta^4$ - and  $\eta^6$ -arene ligands interchanges, giving a new type of fluxionality ( $\Delta G^\ddagger = 67 \text{ kJ mol}^{-1}$  for arene =  $\text{C}_6\text{Me}_6$ ) as indicated in Scheme 23.

Bis(arene) ruthenium complexes (**99**)<sup>2+</sup> are electrophilic and add various nucleophiles (see *Nucleophile*), including hydride, to form (**100**) (Scheme 24). Methyl groups of methylated arene rings are acidic and can be deprotonated, giving the corresponding *exo*-methylene complexes (**101**). This is similar to the chemistry developed for analogous iron complexes, and is reminiscent of the  $\alpha$ -ruthenocenyl carbonium ions (Section 4.5).

## 5.4 Triple-Decker Complexes

Ruthenium has played a central role in the development of 30 valence electron triple-decker cations of the iron group. These compounds were first prepared by Rybinskaya *et al.*,<sup>85,86</sup> through reaction of a 12 valence electron  $[\text{CpRu}]^+$  fragment with a metallocene. The well-known photofragmentation of  $[\text{CpFe}(\text{arene})]^+$  was used to generate  $[\text{FeCp}]^+$ , which was then complexed to ruthenocene in situ. The structure of the triple-decker shows three exactly parallel rings, two of them (one outer and the inner) eclipsed and

Scheme 23

Scheme 24

perfectly staggered to the third one, with Ru–C and Ru–ring distances that on average do not differ significantly from those in ruthenocene or decamethylruthenocene (equation 26).

It was initially thought that the stability of the complexes required permethylation of the Cyclopentadiene (Cp) rings in the middle deck; however, careful choice of the stacking reagent allows for the preparation of partly methylated derivatives as well.<sup>87</sup> Thus, when  $[\text{Cp}^*\text{Ru}]^+$  (as  $(\text{Cp}^*\text{RuOMe})/\text{H}^+$ ) is treated with either pentamethylruthenocene or ferrocene, attack is exclusively at the less-hindered site, making the Cp ring the bridging ligand (equation 27). The stacking reaction proceeds with kinetic control, and the activation barrier for attack at the substituted ring ligand appears to be considerably higher.

## 6 HALF-SANDWICH COMPLEXES (See *Half-sandwich Complexes*)

### 6.1 General Characteristics

Half-sandwich complexes of ruthenium are widespread with both Cp and arene ligands.<sup>65</sup> In the former, electron count considerations dictate the composition of  $\text{CpRuL}_2\text{X}$  or  $[\text{CpRuL}_2]_2$ , where L are usually common  $\pi$ -acceptor ligands and X varies from fluorine to alkyl, hydride, and aryl ligands. If the binding atom in X contains lone pairs, these can substitute for L, leading to bridged structures, such as  $[\text{CpRuLX}]_2$  or even  $[\text{CpRuX}]_4$ , the latter most common with  $\text{X}=\text{S}$ , SR, Se, and so on, but also exemplified by the chloro complex. The oxidation state of ruthenium can be  $\text{Ru}^{\text{II}}$ ,  $\text{Ru}^{\text{III}}$ , and even partially  $\text{Ru}^{\text{IV}}$  in the tetrameric sulfur clusters (see Section 6.4).

It appears as if the potential ligands that can be accommodated in the (arene)Ru series may be even more extended than that in the CpRu series owing to the higher charge and the somewhat harder nature of the central metal, although the oxidation state is as yet confined to  $\text{Ru}^{\text{II}}$ . Apart from the molecular dimers  $[(\eta\text{-arene})\text{RuX}_2]_2$ , the most common starting materials for  $(\eta\text{-arene})\text{Ru}$  chemistry are ionic complexes of the type  $[(\eta\text{-arene})\text{Ru}(\mu\text{-X})_3\text{Ru}(\eta\text{-arene})]^+$ , similar to the closely related Cp\* analogs of the cobalt group. Mononuclear complexes are of the type  $(\eta\text{-arene})\text{RuLX}_2$ ,  $[(\eta\text{-arene})\text{RuL}_2\text{X}]^+$ , and  $[(\eta\text{-arene})\text{RuL}_3]^{2+}$ .

### 6.2 Half-Sandwich Complexes with Cyclopentadienyl Ligands

As outlined above, the most widespread complex type (similar to iron analogs) is  $\text{CpRuL}_2\text{X}$  where  $\text{L} = \text{CO}$ , phosphines, dienes, or other similar ligands and  $\text{X} = \text{hydride}$ , alkyl groups, or halogens. Reaction of  $\text{Ru}_3(\text{CO})_{12}$  with cyclopentadiene in the absence of oxygen yields  $\text{CpRu}(\text{CO})_2\text{H}$ ; the presence of oxygen allows for the synthesis of dimeric  $[\text{CpRu}(\text{CO})_2]_2$  (Scheme 25). Halogenated complexes  $\text{CpRu}(\text{CO})_2\text{X}$ , where  $\text{X} = \text{Cl}$ , Br, or I, are

Scheme 25

formed upon treating  $[\text{CpRu}(\text{CO})_2]_2$  (**102**) with halogenated solvents. The halogen can be substituted with an olefin by reaction with olefins in the presence of  $\text{AlX}_3$ , yielding  $\text{CpRu}(\text{CO})_2\text{L}$ ,  $\text{L} = \text{C}_2\text{H}_4$ ,  $\text{CH}_2 = \text{CHMe}$ , or cyclohexene (Scheme 25). Interestingly, the reaction of  $\text{Ru}_3(\text{CO})_{12}$  with cyclohexene results in a  $\text{Cp}^{\text{Me}}\text{Ru}$  cluster derivative, where the cyclohexene undergoes ring contraction to form a methylcyclopentadienyl ligand on a hexaruthenium hydride cluster  $[\text{Ru}_6(\mu_3\text{-H})(\mu_4\text{-}\eta^2\text{-CO})_2(\text{CO})_{13}(\eta^5\text{-C}_5\text{H}_4\text{Me})]$  (**103**).<sup>88</sup>

Whereas one CO group in complexes of type  $\text{CpRu}(\text{CO})_2\text{Cl}$  is readily substituted for phosphine, bis(phosphine) complexes, for example,  $\text{CpRu}(\text{PPh}_3)_2\text{Cl}$ , are best prepared in a one-step reaction from  $\text{RuCl}_3$ ,  $\text{CpH}$ , and  $\text{PPh}_3$  (equation 28). This air-stable crystalline solid provides a convenient starting point for further transformations.<sup>89,90</sup> The  $\text{CpRu}(\text{PR}_3)_2$  fragment is more nucleophilic than  $\text{CpRu}(\text{CO})_2$ ; thus derivatives of  $\text{CpRu}(\text{PR}_3)\text{X}$  with less electronegative (*see Electronegativity*) X ligands, like alkyl and hydride, are more highly stabilized compared to the respective derivatives of  $\text{CpRu}(\text{CO})_2\text{Cl}$ .

Reduction of (**102**) requires rather strong reducing agents and leads to the anion  $[\text{CpRu}(\text{CO})]^-$  (**104**) (equation 29). This reactivity is qualitatively similar to that of the iron analogs, but the ruthenium complexes are less nucleophilic. Analogous anions with a diene ligand have been prepared and are strong, highly reactive nucleophiles.<sup>91</sup> Substitution of CO by acceptor ligands leads to additional complexes of the same type. All these transformations are also known with substituted Cp ligands.<sup>92</sup>

Half-sandwich ruthenium complexes have the ability to act as substrates for C–C bond cleavage or activation. Treatment of the methylated cyclopentadienyl complex  $[\text{Cp}^*\text{RuCl}_2]_2$  with  $\text{LiAlH}_4$  yields the tetrahydride-bridged complex  $\text{Cp}^*\text{Ru}(\mu\text{-H})_4\text{RuCp}^*$ . Treating this complex with ethylene produces  $\text{Cp}^*\text{Ru}(\text{CH}_2=\text{CH}_2)(\text{CH}=\text{CH}_2)_2\text{RuCp}^*$ , which can undergo C–C coupling in toluene at  $60^\circ\text{C}$  under 1 atm of ethylene to form the dinuclear ruthenacyclopentadiene complex  $\text{Cp}^*\text{Ru}(\text{CH}_2=\text{CH}_2)(\text{CMe}=\text{CHCH}=\text{CMe})\text{RuCp}^*$ .<sup>93</sup>

The 1,5 cyclooctadiene complex  $[\text{Cp}^*\text{Ru}(\eta^2 : \eta^2\text{-C}_8\text{H}_{12})(\text{CO})]\text{OTf}$  was isolated upon treatment of  $\text{Cp}^*\text{Ru}(\eta^4\text{-butadiene})\text{X}$  ( $\text{X} = \text{Cl}, \text{Br}$ ) with butadiene,  $\text{AgOTf}$ , and CO. A similar  $[4 + 4]$  cycloaddition (a thermally forbidden reaction (*see Woodward–Hoffmann Rules*)) is observed when  $\text{Cp}^*\text{Ru}(\text{isoprene})\text{Cl}$  is treated with isoprene,  $\text{AgOTf}$ , and CO. Likewise, the reaction of 1,3-pentadiene with  $\text{Cp}^*\text{Ru}(\eta^4\text{-1,3-pentadiene})\text{Cl}$  results in linear dimerization to form  $[\text{Cp}^*\text{Ru}(4\text{-methyl-(1,3-}\eta^6\text{-8-}\eta^3\text{-nonadienediyl)}]\text{OTf}$ . These types of dimerization occur with both stoichiometric and catalytic amounts of the ruthenium complex.<sup>94</sup>

The trinuclear pentahydride complex  $[\text{Cp}^*\text{Ru}]_3(\mu\text{-H})_3(\mu_3\text{-H})_2$  (**105**) in Scheme 26 consists of ruthenium centers tightly bound by bridging hydrides. Treatment of the pentahydride complex with excess butadiene in THF results in a trinuclear 1-methyl-1,3-dimetallallyl complex  $[\text{Cp}^*\text{Ru}]_3(\text{H})_4[\mu_3\text{-}\eta^3\text{-C}(\text{Me})\text{CHCH}]$  (**106**). This interaction shows the cooperation of all three ruthenium centers as either coordination sites or activation sites. Similar results are found by treating (**105**) with isoprene.<sup>95</sup> Treatment of (**105**) with five equivalents of cyclopentadiene results in bond cleavage of the cyclopentadiene to form a dark purple crystalline solid  $[\text{Cp}^*\text{Ru}(\mu\text{-H})]_3[\mu_3\text{-}\eta_4\text{-C}(\text{Me})=\text{CHCH}=\text{CH}]$  (**107**). In this complex, two of the ruthenium centers act as a coordination site, while the third is an activation site.<sup>96</sup>

### 6.3 Half-Sandwich Complexes with Arene Ligands<sup>97</sup>

As mentioned in Section 3.1, reaction of 1,3- or 1,4-cyclohexadiene derivatives with  $\text{RuCl}_3$  in ethanol yields a brown, highly insoluble polymer of composition  $[(\eta\text{-C}_6\text{R}_6)\text{RuCl}_2]_x$  (equation 30). If this reaction is conducted at ambient temperature, most of the ensuing material is soluble in methylene chloride and consists of the dimer  $[(\eta\text{-C}_6\text{H}_6)\text{RuCl}_2]_2$  (**108**).<sup>98</sup> An improvement of the method uses the readily available natural product  $\alpha$ -phellandrene (5-*i*-propyl-2-methylcyclohexa-1,3-diene) as the cycloidiene in this reaction.<sup>99</sup> The ensuing complex  $[(\eta\text{-}p\text{-cymene})\text{RuCl}_2]_2$  is not only soluble but also can

exchange complexed *p*-cymene for other arene ligands, notably those with a higher degree of alkylation, as shown in equation (31) for hexamethylbenzene. However, not all functionalities seem not to be tolerated in these exchange processes.

The reactivity patterns of the  $(\eta\text{-arene})\text{RuX}_2$  moiety resemble those of the isoelectronic  $\text{Cp}^*\text{RhX}_2$  unit. Thus,

Scheme 26

ionization occurs in hot water to give the chloro-bridged cation (**109**), which can be precipitated as the  $\text{PF}_6^-$  salt (equation 32). The equilibrium in equation (33) is confirmed by NMR, UV, and cyclic voltammetry measurements.

Cleavage of the dimer (**108**) proceeds easily with many donor and acceptor ligands and dehalogenation with  $\text{Ag}^+$  ion in weakly coordinating solvents generates reactive solvent cations  $[(\eta\text{-arene})\text{Ru}(\text{solvent})_3]^{2+}$  for facile complexation. The  $(\eta\text{-arene})\text{Ru}$  moiety accommodates all of the common classical  $\sigma$ -donor ligands along the spectrochemical series as coligands. The ability to bind such N- and O-ligands has been used to complex various amines, imines, Schiff bases, and amino acids to  $(\eta\text{-C}_6\text{H}_6)\text{Ru}$ , generating diastereomeric salts from substituted arene complexes. A notable example of this type is the complex  $(\eta\text{-}p\text{-cymene})\text{RuCl}[(1S,2S)\text{-}N\text{-}p\text{-toluenesulfonyl-1,2-diphenylethanedi-amine}]$  (**110**). When

chiral catalysts of this type are treated with formic acid/triethylamine, they asymmetrically reduce 1,2-diketones to enantiomerically pure chiral 1,2-diols (e.g., benzoin to benzils).<sup>100</sup> These optically active 1,2-diols are valuable in stereoselective organic syntheses and in the production of biologically active compounds.

It should be noted that there is organometallic chemistry associated with the  $(\eta\text{-C}_6\text{H}_6)\text{Ru}$  moiety itself, as exemplified by the orthometalation (*see Orthometalation*) of unsaturated arylphosphine complexes or by the transformations of the dimethyl complex  $(\text{arene})\text{RuMe}_2\text{PR}_3$  (**111a**), which on hydride abstraction rearranges into a cationic (hydrido)ethylene complex (**111b**) (Scheme 27). Much studied is the reaction of  $(\text{arene})\text{RuCl}_2\text{PR}_3$  with alkynes (Scheme 27). The primary acetylides (**112**) are attacked successively by protons and by nucleophiles, commonly alkoxide from a solvent alcohol, to give alkoxycarbene complexes (**113**). The sequence proceeds in one step if the alkyne is added in the presence of  $\text{PF}_6^-$  salt in alcohol solution. If the alkyne bears a hydroxyalkyl group, vinylvinylidene complexes are formed; this method has been extended to conjugated polyene derivatives (**114**).

A unique ruthenium arene complex is produced when  $\text{Ru}_6\text{C}(\text{CO})_{16}\text{PPh}_3$  is refluxed in chlorobenzene. The phosphine complex converts to the  $\eta$ -arene complex  $\text{Ru}_6\text{C}(\text{CO})_{13}[\text{PPh}_2(\mu\text{-}\eta^6\text{-C}_6\text{H}_5)]$  (**115**). In this reversible reaction, the tertiary phosphine ligand becomes  $\eta^6$ -coordinated to the adjacent ruthenium atom. Treatment of the complex with CO at room temperature drives the complex back to the P-bound form.<sup>101</sup>

The indenyl ligand is often viewed as a Cp analog in that it tends to bind to a metal center via its five-membered ring, as shown in  $(\eta^5\text{-C}_9\text{H}_7)\text{RuCl}(\text{cod})$  (**116**). When  $(\eta^5\text{-C}_9\text{H}_7)\text{Ru}(\text{dppm})\text{H}$  was treated with  $\text{CF}_3\text{SO}_3\text{H}$  or  $\text{HBF}_4\cdot\text{Et}_2\text{O}$  at cool temperatures, the  $\eta^2$ -dihydrogen cation  $[(\eta^5\text{-C}_9\text{H}_7)\text{Ru}(\text{dppm})(\text{H}_2)]^+$  was produced. Under the same conditions,  $(\eta^5\text{-C}_9\text{H}_7)\text{Ru}(\text{PPh}_3)_2\text{H}$  produces the dihydrogen cationic complex  $[(\eta^5\text{-C}_9\text{H}_7)\text{Ru}(\text{PPh}_3)_2\text{H}_2]^+$ . Warming either of these complexes to room temperature causes a proton to shift to the indenyl ligand, resulting in the migration of the metal to the six-membered ring of the indene; this is seen in  $[(\eta^6\text{-C}_9\text{H}_8)\text{Ru}(\text{dppm})(\text{H})]^+$  (**117**). The proton migration to the indenyl ligand and rearrangement to the  $\eta^6$ -indene ruthenium complex is the first example of this type.<sup>102</sup>

A more recent addition to the half-sandwich chemistry of ruthenium is given by a number of complexes where the central metal obeys a 16 valence electron count. These coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) metal centers are widely invoked as intermediates or transition states in dissociative substitution processes or in catalytic transformations at transition metal centers. Such complexes are not, however, easily isolated. The most common way to stabilize such species is by coordinating sterically bulky ligands to the metal, thereby preventing further ligand addition. They can also be stabilized in the form of dimeric complexes.

Scheme 27

A common feature of the dimers is a folded Ru–E–Ru–E core (E = O, S, or N) with a dihedral angle between the Ru–E–Ru planes of from 110 to 129°. The butterfly geometry observed in these dimeric complexes results from the retro  $\pi$ -overlap of lone electron pairs into empty metal orbitals and a second-order Jahn–Teller effect (*see Jahn–Teller Effect*) arising from the repulsive interaction of filled metal d-orbitals in a flat ( $D_{2h}$ ) geometry. This type of geometry is exemplified by the crystallographically characterized complex  $[(\eta\text{-}p\text{-cymene})\text{Ru}(\mu_2\text{-}2,6\text{-di-isopropylphenylamido-}N,N)]_2$  (**118**).<sup>103</sup>

#### 6.4 Higher Valent Half-Sandwich Complexes

Although the great majority of research involves ruthenium in oxidation states 0 to II, the organometallic half-sandwich

chemistry of ruthenium also extends to oxidation states III and IV. The Ru<sup>III</sup> complex (**119**) is formed in the same way as its rhodium analog, that is, by heating RuCl<sub>3</sub> with Cp<sup>\*</sup>H in methanol or ethanol (Scheme 28).<sup>104–106</sup> This complex is the most widespread starting material in nearly all preparations containing alkylcyclopentadienyl ruthenium complexes. Complex (**119**) had long been considered a polymer before structural characterization revealed a chloride-bridged dimer. A unique feature of the solid-state structure of this compound, schematically indicated in Scheme 28, was the presence of two isomeric forms in the solid, a paramagnetic isomer with a long, nonbonding Ru–Ru separation of 3.75 Å, and one with a shorter Ru–Ru separation of 2.93 Å. In the latter isomer, the Ru<sup>III</sup> d<sup>5</sup> centers strongly interact as shown by solid-state NMR to form a diamagnetic (*see Diamagnetism*) complex. In solution, these forms rapidly interconvert in a temperature-dependent equilibrium, as indicated by a

large temperature-dependent chemical shift of the averaged Pentamethylcyclopentadiene ( $\text{Cp}^*$ ) signal (opposite to the temperature dependence of the magnetic susceptibility). This latter phenomenon has been used to prove the presence of similar isomers in solution in those cases where only one form is detected in the solid state.

A  $\text{Ru}^{\text{IV}}$  center has been encountered in  $\text{Cp}^*\text{Ru}(\eta^4\text{-}2,3\text{-disubstituted-1,3-butadiene})\text{Br}_2$  complexes (**120**). These

Scheme 28

compounds are synthesized by the oxidative addition (*see Oxidative Addition*) of  $\text{Br}_2$  to  $\text{Cp}^*\text{Ru}(\eta^4\text{-diene})\text{Br}$  complexes. Interestingly, when the diene in the starting material is 1,3-butadiene, or either monosubstituted- or 1,2-disubstituted-1,3-butadiene, a neutral dibromoruthenium(IV) ( $\eta^3\text{-allyl}$ ) complex is formed. In this complex, the allyl assumes an *anti* conformation (**121**). When the starting material involves 1,4-disubstituted-1,3-butadiene, the same  $\eta^3\text{-allyl}$  complex is formed but with a *syn* configuration (**122**).<sup>107</sup> The complete series of trihalo ruthenium(IV) complexes  $(\text{Cp}^*\text{RuX}_3)_n$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) are obtained from allowing (**119**) to react with the respective halogen.<sup>108</sup>

## Glossary

*S-Donor ligand:* molecule in which a sulfur atom is directly bonded to a metal center

## Abbreviations

porph = Porphyrin; pz = Pyrazine; [9]aneS<sub>3</sub> = 1,4,7-trithiacyclononane; [14]aneN<sub>4</sub> = 1,4,7,11-tetraazacyclotetradecane; [18]aneS<sub>6</sub> = 1,4,7,10,13,16-hexathiacyclooctadecane; [18]aneO<sub>6</sub> = 1,4,7,10,13,16-hexaoxacyclooctadecane; [9]aneN<sub>3</sub> = 1,4,7-triazacyclononane.

## 1 INTRODUCTION AND GENERAL FEATURES

A very extensive literature has developed concerning the chemistry of S-coordination compounds. A general feature of S-donor ligands is their ability to bind to a very wide variety of metal centers, particularly of the second and third row transition metals, to form mononuclear, polynuclear, and cluster compounds. Polysulfides S<sub>n</sub><sup>2−</sup>, thiolates RS<sup>−</sup>, and related anionic S-donors are generally regarded as strong  $\sigma$ - and  $\pi$ -donors. In addition, owing to their polarizability, these S-donor ligands can form a range of polynuclear complexes in which the S-atoms bridge between two metal ions, or face-cap three or more metal centers.<sup>1</sup> The formation of metal clusters is, therefore, a common and extremely

important aspect of S-coordination chemistry, particularly since complexes of Fe, Mo, Cu, and Ni are present at the active sites of several metalloenzymes (*see Iron–Sulfur Models of Protein Active Sites; Iron–Sulfur Proteins; Nickel Enzymes & Cofactors; Nickel: Models of Protein Active Sites; Nitrogenase: Metal Cluster Models and Polynuclear Organometallic Cluster Complexes*). Binding of soft anionic S-donors to soft metal centers is consistent with hard–soft acid–base principles, although covalency in metal–sulfur binding is also important. Thiolate RS<sup>−</sup> and hydrosulfide HS<sup>−</sup> ligands occur between F<sup>−</sup> and Cl<sup>−</sup> in the spectrochemical series reflecting their strong  $\pi$ -donor capacity and their abilities to stabilize relatively high metal oxidation states, for example, Mo<sup>VI</sup>.

In contrast, thioethers of the type R<sub>2</sub>S are generally poor donors to metals centers, the stability of complexes decreasing in the order S<sup>2−</sup> > RS<sup>−</sup> > R<sub>2</sub>S (Scheme 1). Macrocyclic ligands tend to form complexes of increased thermodynamic stability and kinetic inertness compared to their open-chain analogs (*see Macrocyclic Ligands*).<sup>2–4</sup>

The relative  $\pi$ -acceptor and  $\pi$ -donor properties of thioether S-donors have been discussed (Scheme 2), and, although weak, their  $\pi$ -acceptor abilities can contribute to the stabilization of low-valent metal states, for example, Mo<sup>0</sup>.<sup>2</sup> Thioether ligands, R<sub>2</sub>S, are normally found between H<sub>2</sub>O and NH<sub>3</sub> in the spectrochemical series, although certain macrocyclic thioether complexes appear to have ligand fields approaching those expected for tertiary phosphine ligands; macrocyclic ligands often impose specific bonding, stereochemical, and conformational restrictions upon the resultant complexes (*see Section 8*).<sup>2–4</sup>

A series of reviews on S-donor ligands has been published and these are referred to in the appropriate sections below. Reviews on general aspects of S-coordination chemistry have appeared,<sup>5,6</sup> while inorganic texts give good, general overviews on the subject.<sup>7</sup> Comprehensive accounts of S-donor ligands have been published.<sup>8</sup> A

Scheme 1

Scheme 2

review of sulfur donor ligands with transition metal complexes to generate homogeneous catalysts has recently appeared.<sup>9</sup>

## 2 H<sub>2</sub>S, RSH, AND HS<sup>−</sup> LIGANDS

Unlike H<sub>2</sub>O, H<sub>2</sub>S rarely forms simple complexes with transition metal ions owing to facile deprotonation to HS<sup>−</sup> and S<sup>2−</sup>. Additionally, reaction of H<sub>2</sub>S with simple metal salts often leads to reduction of the metal and/or the formation of insoluble metal sulfides. A number of H<sub>2</sub>S complexes have been reported including [Mn(η-C<sub>5</sub>H<sub>5</sub>)(CO)<sub>2</sub>(SH<sub>2</sub>)] (**1**), [W(CO)<sub>5</sub>(SH<sub>2</sub>)] (**2**), [Ru(NH<sub>3</sub>)<sub>5</sub>(SH<sub>2</sub>)]<sup>2+</sup> (**3**), and the tetrahedral [AlBr<sub>3</sub>(SH<sub>2</sub>)] (**4**). The coordinated H<sub>2</sub>S ligand in [W(CO)<sub>5</sub>(SH<sub>2</sub>)] can be alkylated with diazoalkanes to give the corresponding thioether complexes [W(CO)<sub>5</sub>(SR<sub>2</sub>)] (R = Me, Et). The chemistry of hydrogen sulfide with palladium and ruthenium has been the subject of a short review.<sup>10</sup>

Syntheses of complexes incorporating the hydrosulfide HS<sup>−</sup> ligand have to avoid the formation of S<sup>2−</sup>, species which can oligomerize to give clusters and polymers. The modes of coordination of HS<sup>−</sup> to metal centers are given in Scheme 3.

Deprotonation of coordinated H<sub>2</sub>S occurs readily to afford species such as [Ru(NH<sub>3</sub>)<sub>5</sub>(SH)]<sup>2+</sup> (**5**), [Ni(η-C<sub>5</sub>H<sub>5</sub>)(P-*n*-Bu<sub>3</sub>)(SH)] (**6**), [Cr(OH<sub>2</sub>)<sub>5</sub>(SH)]<sup>2+</sup> (**7**), and [W(CO)<sub>5</sub>(SH)]<sup>−</sup> (**8**). Oxidative addition of H<sub>2</sub>S to Pt<sup>0</sup> starting materials affords trans-addition products such as *trans*-[Pt(H)(PEt<sub>3</sub>)<sub>2</sub>(SH)] (**9**), while *trans*-[Pt(PEt<sub>3</sub>)<sub>2</sub>(SH)<sub>2</sub>] (**10**) has also been isolated.

Binuclear and polynuclear species incorporating the HS<sup>−</sup> ligand have been reported, including [M<sub>2</sub>(CO)<sub>10</sub>(μ-SH)]<sup>−</sup> (**11**; M = Cr, Mo, W), [Mn<sub>2</sub>(CO)<sub>8</sub>(μ-SH)<sub>2</sub>] (**12**), [Fe<sub>2</sub>(L)<sub>2</sub>(μ-SH)<sub>3</sub>]<sup>+</sup> (**13**); L = bis(2-diphenylphosphinoethyl)phenylphosphine, and the proposed cubane complex [PtMe<sub>3</sub>(SH)]<sub>4</sub>

Scheme 3

(**14**). Polymeric hydrosulfide complexes have been reported for the complex [Co(SH)([14]aneN<sub>4</sub>)](ClO<sub>4</sub>) ([14]aneN<sub>4</sub> = 1,4,7,11-tetraazacyclotetradecane) where the macrocyclic donors adopt the equatorial positions with the Co<sup>II</sup> ions bridged by hydrosulfide anions positioned at the axial sites.<sup>11</sup> Hydrosulfido complexes of transition metals have been reviewed with emphasis being placed on the reactivities of hydrosulfido complexes, including nucleophilic reactions, oxidative coupling, and sulfide cluster formation.<sup>12</sup> The hydrogenation and hydrogenolysis of thiophenic molecules catalysed by soluble

### Scheme 4

metal complexes has been reviewed and the mechanistic information has been related to heterogeneous hydrodesulfurization catalysis.<sup>13</sup>

### 3 SULFIDES: $S_N^{2-}$ (See Sulfur: Inorganic Chemistry)

### 3.1 Monosulfide: $S^{2-}$

The coordination chemistry of the sulfido ligand  $\text{S}^{2-}$  is very varied. Scheme 4 illustrates the modes of coordination of  $\text{S}^{2-}$  to transition metal ions. The monosulfido ligand can act as a two-electron, terminal or  $\mu_2$ -bridging donor, or up to a six-electron donor if it binds as  $\mu_4$ -bridging or interstitial donor. It is, therefore, not surprising that a wide variety of binuclear and polynuclear sulfido clusters complexes can be prepared.

Terminally bound sulfide  $\text{S}^{2-}$  is commonly found in a wide range of metallothio anions, particularly of  $\text{d}^0$  metal centers for example  $[\text{MS}_4]^{3-}$  ( $\text{M} = \text{V}, \text{Nb}, \text{Ta}$ ),  $[\text{MS}_4]^{2-}$  ( $\text{M} = \text{Mo}, \text{W}$ ), and  $[\text{ReS}_4]^-$ . The mixed thiooxy and thioseleno anions  $[\text{MS}_{4-x}\text{O}_x]^{n-}$  and  $[\text{MS}_{4-x}\text{Se}_x]^{n-}$  have also been prepared. Additionally, metalloanions can coordinate to other metal centers, so behaving as ligands in their own right. Thus, a wide range of mixed metal clusters and oligomers incorporating bridging  $\text{S}^{2-}$  ligands can be prepared. Examples of metallothio anion complexes are given in Scheme 5.

Some complexes incorporating  $\mu_2$ -,  $\mu_3$ -, and  $\mu_4$ -bridging  $S^{2-}$  ligands are illustrated in Scheme 6. Important examples include  $[(OC)_2(Cp)Cr\equiv Cr(Cp)(CO)_2]$  (**15**) incorporating a linear triply bonded  $Cr\equiv Cr$  unit, Roussin's red anion  $[Fe_2(NO)_4(\mu_2-S)_2]^{2-}$  (**16**),  $[Fe_4S_4(Cp)_4]$  (**17**), and

Complexes incorporating thiol RSH ligands are rare since deprotonation at the coordinated S-donor is relatively facile, although  $[\text{Ru}(\text{NH}_3)_5(\text{SEt})]^{2+}$  and  $[\text{Fe}(\text{TPP})(\text{SPh})(\text{SPhH})]$  have been reported.

### Scheme 5

Scheme 6

$[\text{Fe}_4\text{S}_6(\text{Cp})_4]$  incorporating  $\text{S}_2^{2-}$  and  $\text{S}_2^{2-}$  moieties. Two reviews describing the use of  $[\text{Cp}'_2\text{M}_2\text{S}_4]$  (where  $\text{M} = \text{Fe}$  or  $\text{Ru}$  and  $\text{Cp}' = \text{cyclopentadienyl}$  or substituted cyclopentadienyl) as a building block for a host of multinuclear transition metal clusters have been published.<sup>14,15</sup>

(15)

(16)

(17)

An enormous range of metal-sulfur cluster compounds derived from covalently linked cubane clusters and/or oligomers of metallothio anions has been prepared. Many

have been found to be redox active and act as electron sinks via multielectron transfer processes. The electrochemistry of these systems has been comprehensively reviewed.<sup>16</sup>

One of the most important structural motifs in metal-sulfido cluster chemistry is the  $\text{M}_4\text{S}_4$  cube.  $\text{Fe}_4\text{S}_4$  cubane clusters have been studied in relation to biological systems in terms of substitution and redox chemistry. For example, the one-electron reduction of  $[\text{Fe}_4\text{S}_4(\text{SR})_4]^{2-}$  (18) to  $[\text{Fe}_4\text{S}_4(\text{SR})_4]^{3-}$  leads to a structural reorganization of the cubane structure from  $D_{2d}$  compressed to elongated  $D_{2d}$  (Scheme 7).<sup>17</sup> Scheme 8 shows subsite-specific reactions that have been reported at the  $[\text{Fe}_4\text{S}_4]$  core.<sup>18</sup> The nature of the  $[\text{4Fe-4S}]$  and  $[\text{3Fe-4S}]$  cubane cluster in metalloenzymes such as ferredoxins, aconitase, nitrogenase, hydrogenases, and sulfite reductase are major areas of research interest. The chemical interconversion of  $[\text{4Fe-4S}]$  and  $[\text{3Fe-4S}]$  clusters has allowed the synthesis of heteroatom clusters of type  $[\text{3FeM'-4S}]$  (equation 1).

(18)

A very wide range of higher metal–sulfur clusters has been prepared for example,  $[\text{Ni}_9(\mu_4\text{-S})_3(\mu_3\text{-S})_6(\text{PET}_3)_6]^{2+}$  (**19**),<sup>11</sup>  $[\text{Ni}_3(\mu_3\text{-S})_2(\text{PET}_3)_6]^{2+}$  (**20**), and  $[\text{Ni}_3(\mu_3\text{-S})_2(\text{SH})(\text{PET}_3)_5]^{2+}$  (**21**).<sup>12</sup>

Scheme 7

(19)

Scheme 8

### 3.2 Disulfide: S<sub>2</sub><sup>2-</sup>

In general, complexes of S<sub>2</sub><sup>2-</sup> can be prepared by reaction of elemental sulfur with electron-rich metal centers, by high-temperature reaction of metal complexes with S<sub>2</sub>Cl<sub>2</sub> and S<sub>8</sub>, or by direct reaction of metal salts with polysulfides. The binding of S<sub>2</sub><sup>2-</sup> to transition metals can be compared to the binding of O<sub>2</sub>:  $\sigma$ -donation occurs from the filled  $\pi$ -orbital of the S<sub>2</sub><sup>2-</sup> fragment coupled to  $\pi$ -donation from the  $\pi^*$ -antibonding orbital on S<sub>2</sub><sup>2-</sup> to the metal d $_{\pi}$ -orbitals (Scheme 9). Thus, coordination to a metal ion leads to a shortening of the S-S distance in S<sub>2</sub><sup>2-</sup> and makes this fragment more susceptible to nucleophilic attack. The redox interconversion of coordinated S<sub>2</sub><sup>2-</sup> and S<sub>2</sub><sup>2-</sup> to give S<sub>2</sub> (equation 2) is of relevance to the action of desulfurization catalysts and to related biological processes.

Scheme 9

Scheme 10

Scheme 10 illustrates the range of coordination modes of S<sub>2</sub><sup>2-</sup> to metal centers, while Scheme 11 illustrates some the complexes that have been characterized.

An unusual  $\mu$ - $\eta^1$ -S<sub>2</sub> ligand has been stabilized in the complex [Fe<sub>2</sub>(S<sub>2</sub>)<sub>3</sub>([9]aneN<sub>3</sub>)<sub>2</sub>] ([9]aneN<sub>3</sub> = 1,4,7-triazacyclononane). The persulfide ligands are stabilized via hydrogen-bonding to the amine hydrogen atoms, and the polarized structure for the persulfide ligands is supported by their reaction with methyl iodide.<sup>19</sup>

### 3.3 Polysulfides: S<sub>x</sub><sup>2-</sup>

The coordination chemistry of polysulfides has been reviewed<sup>20</sup> and has been developed for the synthesis of new chalcogenide materials.<sup>21</sup> Polysulfide ligands S<sub>x</sub><sup>2-</sup> ( $x = 2-9$ ) form a remarkable range of metal complexes which are usually prepared by reaction of metal salts with either elemental sulfur and/or with polysulfides. Scheme 12 illustrates some of the polysulfide complexes that have been prepared and characterized. The complex [Ti(Cp)<sub>2</sub>(S<sub>5</sub>)] is a versatile starting material and reagent for the synthesis of a wide variety of compounds (Scheme 13). [Ti(Cp)<sub>2</sub>(S<sub>5</sub>)] and [Ti(Cp)<sub>2</sub>(S<sub>3</sub>)] are both fluxional in solution, showing a ring flipping of the polysulfide ring (equations 3 and 4).<sup>22</sup>

Scheme 11

Scheme 12

Scheme 13

Reaction of [Os(PMe<sub>3</sub>)<sub>3</sub>(H)(CH<sub>2</sub>PMe<sub>2</sub>)] with elemental S affords two products [Os(PMe<sub>3</sub>)<sub>3</sub>(S<sub>6</sub>)] and [Os(PMe<sub>3</sub>)<sub>3</sub>(S<sub>7</sub>)] (**22**), the latter incorporating a tridentate S<sub>7</sub><sup>2-</sup> ligand.<sup>23</sup> Likewise, reaction of [Os(S<sub>2</sub>CNR<sub>2</sub>)<sub>3</sub>] with elemental S affords [Os<sub>2</sub>(S<sub>5</sub>)(S<sub>3</sub>CNR<sub>2</sub>)(S<sub>2</sub>CNR<sub>2</sub>)<sub>5</sub>] (**23**; R = Et) in which an S<sub>5</sub><sup>2-</sup> chelate has been formed, and an S has been incorporated into one of the dithiocarbamate, S<sub>2</sub>CNR<sub>2</sub>, ligands to give coordinated S<sub>3</sub>CNR<sub>2</sub>.<sup>23</sup> The dinuclear species [Os<sub>2</sub>(S<sub>3</sub>CNEt<sub>2</sub>)<sub>2</sub>(S<sub>2</sub>CNEt<sub>2</sub>)<sub>3</sub>]<sup>+</sup> (**24**) has been isolated from the reaction of [OsCl<sub>6</sub>]<sup>2-</sup> with NaS<sub>2</sub>CNEt<sub>2</sub>.

#### 4 THIOLATES: $\text{RS}^-$

Comprehensive reviews on the coordination chemistry of thiolates and hindered thiolates have appeared.<sup>24,25</sup> One of the major problems in preparing complexes is oxidation of the thiolate to the corresponding disulfide. This can be more readily controlled with hindered thiolates, which can stabilize highly reactive, coordinatively unsaturated complexes. An important feature of thiolates is their ability to level charge within metal complexes. Thus, both  $\pi$ -acceptor (d-orbital on S, or S-C  $\sigma^*$ -orbital) and  $\pi$ -donor (lone pair on S) properties

Scheme 14

of thiolates have been discussed in relation to the degree of electron density at the metal center(s). The tendency for  $\text{S} \cdots \text{S}$  interactions and the polarizability of S-donors contrasts with the chemistry of the corresponding O-donor alkoxides. Scheme 14 illustrates the bonding modes of thiolates,  $\text{RS}^-$ , to transition metal centers.

Thiolates,  $\text{RS}^-$ , can bind terminally in octahedral  $[\text{OsCl}(\text{PPhMe}_2)_3(\text{N}_2)(\text{SC}_6\text{F}_5)]$  (**25**), tetrahedral  $[\text{M}(\text{SR})_4]^{2-}$  (**26**) ( $\text{M} = \text{Fe}, \text{Co}, \text{Ni}, \text{Zn}, \text{Cd}, \text{Hg}$ ), square-planar  $[\text{Pd}(\text{SR})_4]^{2-}$  (**27**), trigonal planar  $[\text{M}(\text{SPh})_3]^-$  (**28**) ( $\text{M} = \text{Cu}, \text{Hg}$ ), and linear structures  $[\text{Hg}(\text{SR})_2]$  (**29**) ( $\text{R} =$  for example,  $\text{Ph}, \text{SC}_6\text{F}_5, \text{SC}_6\text{Cl}_5, \text{SEt}_3$ ).

The synthesis, structures, and reactivities of metal thiolates with group 4 and 5 metals,<sup>26</sup> and the synthesis and study of copper-thiolates<sup>27</sup> have been reviewed.  $\text{Hg}^{\text{II}}$  thiolate chemistry has been reviewed and related to the binding of  $\text{Hg}^{\text{II}}$  in vivo by metalloregulatory proteins.<sup>28</sup> A range of two-, three-, and four-coordinate  $\text{Hg}^{\text{II}}$  thiolate complexes has been prepared, and comparisons with the metalloregulatory protein,  $\text{Hg-MerR}$ ,

suggest that the latter involves a trigonal planar  $[\text{Hg}(\text{SCys})_3]^-$  model. A ligand composed of *p-tert*-butylcalix[4]arene backbone bearing two thiol and two dodecyloxy- groups displays selective extraction of  $\text{Hg}^{\text{II}}$  from aqueous solution over  $\text{Cd}^{\text{II}}$  and  $\text{Pb}^{\text{II}}$ .<sup>29</sup> Scheme 15 illustrates some terminally bound thiolate complexes.  $\text{Au}^{\text{I}}$  thiosugar complexes and thiomalate complexes are used for the treatment of rheumatoid arthritis. Bridging thiolate ligands have been also observed and some complexes are given in Scheme 16.

Inversion at the S-donors of thiolates (Scheme 17) can be monitored by NMR spectroscopy and the activation energies for these fluxional processes have been assessed for a range of complexes (equation 5).<sup>30</sup>

Scheme 15

Scheme 15 cont'd

Pendant arm macrocycles with thiolate arms have been synthesized and shown to encapsulate  $\text{Ga}^{\text{III}}$  and  $\text{In}^{\text{III}}$  octahedrally.<sup>31</sup>

A recent major impetus for the study of S-donor complexes has been provided by the discovery of paramagnetic Ni centers in several biological systems (see Section 9). Several mixed N/S-donor complexes have been prepared and characterized, including  $[\text{Ni}(\text{terpy})(\text{SPh})_2]_2$  (**30**),  $[\text{Ni}(\text{terpy})(\text{SC}_6\text{F}_5)_2(\text{NCMe})]$  (**31**),  $[\text{Ni}(\text{terpy})(\text{SR})_2]$  [ $\text{R} = 2,4,6\text{-}i\text{-Pr}_3\text{C}_6\text{H}_2$  (**32**);  $2,6\text{-Me}_2\text{C}_6\text{H}_3$  (**33**)], and their chemical and redox properties have been related to the *in vivo* systems.<sup>32</sup>

Holm and coworkers have investigated the structural and redox properties of a related series of mixed N/S-donor  $\text{Ni}^{\text{II}}$  complexes, for example (**34**) and (**35**), and have generated

and studied the corresponding  $\text{Ni}^{\text{III}}$  species.<sup>33</sup> The binuclear nickel-thiolate macrocyclic complex (**36**) displays a one-electron oxidation to yield a  $\text{Ni}^{\text{III}}\text{Ni}^{\text{II}}$  species with significant delocalization of the unpaired electron density onto the bridging thiolate ligands but not onto the second nickel ion. Thus, the charge delocalization in this complex lies between the two redox extremes of nickel(III)-thiolate and nickel(II)-thiyl radical.<sup>34</sup> Redox studies on a series of metal bound thiolates such as (**37**) demonstrate their oxidation to sulfones and then to the sulfoxides. All the complexes display a reversible  $\text{Ni}^{\text{II}}\text{-Ni}^{\text{I}}$  reductive couple with the thiolate complexes also showing an irreversible ligand-based oxidation presumably to an unstable thiyl radical species. The

Scheme 16

bis(sulfone) complexes additionally show a reversible  $Ni^{II}$ - $Ni^{III}$  oxidative process as do the analogous complexes where the sulfur has been alkylated. The possibility for a two centred  $Ni$ -SR site to function in oxidative-addition reactions was suggested as an intriguing solution by Nature to achieve this type of reactivity.<sup>35</sup>

Scheme 17

The Ru diazene binuclear complex (**38**) represents an important model for the activation of  $\text{N}_2$  with  $\text{N-H}\cdots(\text{S-thiolate})_2$  interactions being vital to stabilisation of the diazene ligand.<sup>36</sup> Furthermore, the amino-thiolate Ru complex (**39**) incorporating bound dinitrogen can be prepared under mild conditions by exchange of a bound MeCN ligand.<sup>37</sup> Related Fe amino-thiolate complexes have also been shown to stabilize diazene fragments and the observed strong coupling of the  $\text{H}^+/\text{e}^-$  flux in these systems has been related to the mechanism of the nitrogenase FeMo cofactor.<sup>38</sup>

The  $\text{Fe}^{\text{II}}$  complex of 4,6-di-*tert*-butyl-2-aminothiophenol has been characterized crystallographically with the ligand in *o*-aminothiophenolate(1-), aromatic *o*-iminothiophenolate dianionic (2-) and open-shell *o*-iminothionebenzosemiquinone (1-) forms. Zero-field Mossbauer spectroscopy unambiguously confirms the presence of high-spin ferrous ions throughout.<sup>39</sup>

The aggregation of  $\text{Ni}^{\text{II}}$  thiolate complexes yields homohexanuclear and heteropentanuclear complexes.<sup>40,41</sup> Fascinating pinwheel motifs have been observed with ligands such as (**40**) and (**41**) in which two  $\text{Ni}^{\text{II}}$  ions bridge four  $\text{Ni}^{\text{II}}$  amino-thiolate complexes. Alternatively, heteropentanuclear or heterohexanuclear complexes are realized where two  $\text{Cu}^{\text{I}}$

ions or two  $\text{Pd}^{\text{II}}$  ions bridge three or four  $\text{Ni}^{\text{II}}$  amino-thiolate complexes, respectively. Both the bite angle of the  $\text{S}^-$ -Ni-S $^-$  unit and the choice of bridging metal ion influence whether a simple trinuclear aggregate or a higher motif is favored.

The isomers of  $[\text{Co}(\text{L-cys})(\text{en})_2](\text{NO}_3) \cdot \text{AgNO}_3$  have been structurally characterized. Significantly, the structure derived from  $\Delta_{\text{L}}\text{-}[\text{Co}(\text{L-cys})(\text{en})_2]^+$  leads to a two-dimensional sheetlike structure, while  $\Delta_{\text{L}}\text{-}[\text{Co}(\text{L-cys})(\text{en})_2]^+$  affords a one-dimensional left-handed helix, where the left-handed helicity is predetermined by the chiral configuration in the starting  $\text{Co}^{\text{III}}$  complex.<sup>42</sup>

Scheme 18

## 5 DITHIOLENES

The coordination chemistry of 1,2-dithiolenes and related ligands has been reviewed.<sup>25,43</sup> 1,2-Dithiolenes are bidentate, redox-active ligands which can coordinate in the limit as dithiodiketones or dithiolates (Scheme 18). Scheme 19 illustrates the more common dithiolene ligands that have been investigated. Syntheses of these ligands are well established and are usually based upon derivatization of dihalo and ketonic starting materials (Scheme 20).

The coordination chemistry of dithiolenes is extensive with square-planar  $[\text{M}(\text{L})_2]^{x+}$  (**42**) and tris-chelate complexes  $[\text{M}(\text{L})_3]^{x+}$  (**43**) being prevalent. The latter are interesting since they tend to adopt trigonal prismatic rather than the much more common octahedral geometry, the driving force being thought to be attractive intraligand S–S interactions. The square-planar complexes  $[\text{M}(\text{L})_2]^{x+}$  can form five-coordinate adducts or oligomers via M–S bridges (equations 6 and 7). The formation of redox oligomers and related

Scheme 19

Scheme 20

Scheme 21

complexes showing stacked structures in the solid state has led to the formation of one-dimensional conductors, partially oxidized/reduced conducting polymers, and charge-transfer salts. Liquid crystal dithiolenes have also been prepared. Many dithiolene complexes are redox active, and the interpretation of these electron-transfer processes as being metal or ligand based has been controversial. The problems of assignment stem from the facile electron transfer of dithiolene ligands themselves, and delocalization of charge density across the ligand and metal centers.

Scheme 21 illustrates some of the dithiolene complexes that have been prepared. The coordination chemistry of ligands derived from benzene-1,2-dithiolate has been investigated with Fe and Ru centers for the potential binding of  $N_2$  and  $N_2H_4$  as models for nitrogenase (see **Nitrogenase: Metal Cluster Models**).<sup>36,44</sup>

$Ni^{II}$  dithiolenes have been shown to be effective for the electrochemical separation of alkenes from complex streams. No poisoning was observed in the presence of  $H_2$ , CO, acetylene, or  $H_2S$  with binding of alkene to the sulfur ligands rather than to Ni (Scheme 22). This reflects the radical nature of dithiolenes in these complexes.<sup>45</sup> Metal bis-1,2-dithiolene complexes may also act as conducting or magnetic assemblies.<sup>46</sup>

A general route to asymmetric dithiolenes has been developed and has been used for the generation of the dithiolene complexes  $[MO(dithiolene)_2]^{2-}$  ( $M = Mo$  or  $W$ ).<sup>47</sup> These complexes have been developed to explore the chemistry of Mo and W when bound to pterin ligands in biology, for example in the molybdenum cofactor of DMSO reductase or in aldehyde oxidoreductase. A comprehensive study of 25 complexes  $[W^{IV}(OC_6H_4-p-X')(S_2C_2(C_6H_4-p-X)_2)_2]^{1-}$  ( $X = Br, F, H, Me, OMe$  and  $X' = CN, Br, H, NH_2$ ) has been reported and their relevance to the mechanism of oxygen atom transfer in the DMSO reductase isoenzyme

Scheme 22

described. A stepwise oxo-transfer reaction is proposed in an early transition state in which primary  $W^{IV}-O(\text{substrate})$  bond-making is rate-limiting. This is followed by a six-coordinate structure with another transition state involving both atom and electron transfer to yield an  $W^{VI} = O$  group.<sup>48</sup> Monodithiolene complexes of  $Mo^V$  and  $Mo^{VI}$  have been synthesized as structural analogs of the oxidized form of the sulfite oxidase enzyme family.<sup>49</sup>

## 6 MIXED S/O, S/N AND P/S LIGANDS

The coordination chemistry of NS (thionitrosyl), thiazate ( $NSO^-$ ), disulfidothionitrate ( $S_3N^-$ ), sulfur monoxide (SO), disulfur monoxide ( $S_2O$ ),  $SO_2$ , DMSO, thiosulfate, sulfite, and thiourea ligands is extensive.<sup>50-52</sup> Scheme 23 illustrates their coordination modes and some of the complexes that can be generated.

The transition metal coordination chemistry of P/S ligands<sup>53</sup> and of thiophosphorus and thio arsenic ligands bound to transition metals and main group elements<sup>54</sup> have been summarized. An interpenetrating diamond-type framework has been prepared from the high-temperature solid-state reaction of U,  $P_2S_5$ , and S to yield  $UP_4S_{12}$ . This material contains  $U^{IV}$  ions linked by  $S, S'$ -bidentate  $P_2S_6^{2-}$  molecular rods.<sup>55</sup> Extended S-donor ligand such as (44) can generate novel polymeric network materials.<sup>56</sup>

Scheme 23

Scheme 23 cont'd

## 7 DITHIOCARBAMATES AND RELATED LIGANDS

The chemistry of dithiocarbamates, thioacids, and related ligands,<sup>57</sup> dithiolium and dithio- $\beta$ -diketonate ligands,<sup>58</sup> thiooxalates,<sup>59</sup> and  $\text{CS}_2$ <sup>60</sup> has been reviewed. Scheme 24 illustrates the dithiocarbamate ligands that have been studied; complexes of monothio derivatives have also been investigated. The ligands are generally prepared by reaction of  $\text{CS}_2$  or COS with the corresponding amine. A range of dithiocarbamate complexes, including  $[\text{M}(\text{S}_2\text{CNR}_2)_2]$  (45) ( $\text{M} = \text{Ni}, \text{Pd}, \text{Pt}$ ) and  $[\text{M}(\text{S}_2\text{CNR}_2)_3]$  (46) ( $\text{M} = \text{Fe}, \text{Ru}, \text{Os}$ ), have been prepared. Dithiocarbamates can also bridge between two metal ions, as in  $[\text{Ru}_2(\text{S}_2\text{CNR}_2)_5]^+$ , which exists as two isomers, the  $\alpha$  form (47) and  $\beta$  form (48). The complexes  $[\text{Zn}(\text{S}_2\text{CNMe}_2)_2]$  and  $[\text{Fe}(\text{S}_2\text{CNMe}_2)_3]$  and the disodium salt  $\text{Na}_2[\text{S}_2\text{CNHCH}_2\text{CH}_2\text{NHCS}_2]$  have been marketed as fungicides under the names Ziram, Ferbam, and Nabam, respectively.

Scheme 24

Scheme 25

Fe dithiocarbamates are enjoying a resurgence of interest in their chemistry following their application in the detection and analysis of biological NO produced endogenously from NO synthase.<sup>61</sup> Dithiocarbamates have been found to form complexes with Au<sup>II</sup> ions as in binuclear complexes, [Au<sub>2</sub>(S<sub>2</sub>CNR<sub>2</sub>)<sub>2</sub>X<sub>2</sub>] and [Au<sub>2</sub>(S<sub>2</sub>CNR<sub>2</sub>)(CH<sub>2</sub>PPh<sub>2</sub>CH<sub>2</sub>)X<sub>2</sub>].<sup>62</sup>

Mono-, dithio- $\beta$ -diketonate, and related ligands are effective chelates for a wide range of metal ions, forming complexes of the type [M(L)<sub>2</sub>] (**49**) (M = Co, Ni, Pd, Pt, Zn, Cd, Hg) and [M(L)<sub>3</sub>] (**50**) (M = Cr, Fe, Ru, Os, Co, Rh, Ir). The complexes are often redox active, and like those of dithiolenes, the location of redox activity in terms of metal- or ligand-based radicals has been the subject of much interest.

Scheme 26

## 8 THIOETHERS: R<sub>2</sub>S

The coordination chemistry of thioethers has been reviewed.<sup>2-4</sup> They are generally poor ligands and highly labile, and so can be used as leaving groups for metal complex syntheses. For example, [Au(tht)<sub>2</sub>]<sup>+</sup> (**54**; tht = tetrahydrothiophene) is an effective starting material

A wide range of mono-, di-, tri-, and tetrathiooxalate complexes have been prepared. These species can act as mono-, bi-, tri-, and tetradentate ligands and can also bridge between metal centers (Scheme 25).

CS<sub>2</sub> can bind in monodentate end-on, bidentate chelate, bridging, or  $\eta^2$  forms (Scheme 26). Most complexes of CS<sub>2</sub> are low-valent electron-rich species, for example [Mo(Cp)(CO)<sub>2</sub>( $\eta^2$ -CS<sub>2</sub>)] (**51**), [Ru(CO)<sub>2</sub>(PPh<sub>3</sub>)<sub>2</sub>( $\eta^2$ -CS<sub>2</sub>)] (**52**), and [Pt(PPh<sub>3</sub>)<sub>2</sub>( $\eta^2$ -CS<sub>2</sub>)] (**53**). Conversion of coordinated CS<sub>2</sub> to CS and CS<sub>3</sub> fragments can occur on coordination. The coordination chemistry of phosphine-carbon disulfide adducts (S<sub>2</sub>CPR<sub>3</sub>) has been reviewed; these versatile ligands can act as 2 to 8 electron donors to metal centres.<sup>63</sup>

Scheme 27

Scheme 28

for substitution reactions. Many thioether complexes are fluxional with inversion at the coordinated thioether S-center (Scheme 27). Scheme 28 illustrates some of the thioether

complexes that have been prepared. The fluxionality of thioether and mixed thiolate/thioether ligands has been reviewed.<sup>30</sup> Reviews of complexes of groups 3–6 covering oxidation states greater than 3,<sup>64</sup> and of complexes of the p-block (groups 13–15)<sup>65</sup> with acyclic and macrocyclic thioethers have appeared.

Scheme 29

[9]aneS<sub>3</sub> is unique in that it can be regarded as ‘preorganized’ for facial coordination, and indeed, this ligand forms a range of low-spin, bis-sandwich complexes  $[M([9]aneS_3)_2]^{n+}$  ( $M = Cr, Fe, Ru, Os$  (**55**;  $n = 2$ ),  $Co, Rh, Ir, Ni, Pd$  (**56**;  $n = 2$ ),  $Pt, Zn, Ag, Au, Tl, In$ ). Many of these complexes are redox active, and a series of mononuclear radical species of unusual metal oxidation states can be characterized and isolated, including the Pd<sup>III</sup> radical complex  $[Pd([9]aneS_3)_2]^{3+}$  (**57**).<sup>66</sup> The redox interconversion of Au<sup>I</sup>, Au<sup>II</sup>, and Au<sup>III</sup> centers in  $[Au([9]aneS_3)_2]^{+/2+/3+}$ , (**58**), (**59**), (**60**), respectively, has been reported and illustrates the high coordinative flexibility of thioether crowns.<sup>67</sup>

The hexathioether ligand [18]aneS<sub>6</sub>, the S-analog of 18-crown-6 ([18]aneO<sub>6</sub>), can encapsulate M<sup>II</sup> ions to form highly stable complexes  $[M([18]aneS_6)]^{2+}$  ( $M = Fe; Co, Ni, Cu$  (**61**);  $Pd$  (**62**);  $Pt$ ). The complexes of these ligands with d<sup>8</sup> metal ions such as Pd<sup>II</sup>, Pt<sup>II</sup>, and Au<sup>III</sup> tend to show long-range M⋯S interactions in the range 2.8–3.1 Å. This is reminiscent of the coordination at Cu sites in blue copper proteins such

(60)

(61)

(62)

as azurin and plastocyanin, in which long-range thioether S to Cu distances of some 2.9 Å are observed. The binding of N<sub>2</sub> in the thioether complex *trans*-[Mo(N<sub>2</sub>)<sub>2</sub>(Me<sub>8</sub>[16]aneS<sub>4</sub>)] (63)

has been reported and the ability of homoleptic thioether coordination at Mo<sup>0</sup> to stabilize N<sub>2</sub> binding has been discussed.<sup>68</sup>

(63)

A range of half-sandwich complexes [Pd([9]aneS<sub>3</sub>)Cl(L)] (PF<sub>6</sub>) (L = 2PPh<sub>3</sub>, Ph<sub>2</sub>PCH<sub>2</sub>PPh<sub>2</sub>, Ph<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>PPh<sub>2</sub>, (Ph<sub>2</sub>PCH<sub>2</sub>)<sub>3</sub>CMe, 2,2'-bipyridine or 1,10-phenanthroline) show an approximately square-planar geometry at Pd<sup>II</sup> with two sulfur donors and the ligand L; additionally, there is a weaker interaction to the other apical sulfur.<sup>69</sup>

The chemistry of tridentate mixed azathioether macrocyclic transition metal complexes has recently been reviewed in particular, focusing upon structural and redox properties,<sup>70</sup> and a series of acylurea pendant arm azathioether macrocycles have been developed as heteroditopic receptors for transition metal salts.<sup>71</sup> The first examples of mixed thio- and telluroethers [11]aneS<sub>2</sub>Te, [12]aneS<sub>2</sub>Te and [14]aneS<sub>3</sub>Te, have been prepared. The complex [Ag([11]aneS<sub>2</sub>Te)]BF<sub>4</sub> shows a one-dimensional polymeric chain adopted by the cation, in which the Ag<sup>I</sup> ions are coordinated by three macrocyclic ligands.<sup>72</sup> The transition metal chemistry of alkylcycloarsathianes, in particular, of chain and macrocyclic As-S ligands has been reviewed.<sup>73</sup>

Thiacalixarenes have been observed to form complexes Cu<sub>4</sub>L<sub>2</sub> (L = *p-tert*-butyltetra-thiacalix[4]arene) with both S- and O-binding to Cu. This represents the first example of an intentionally synthesized paramagnetic koiland, that is hollow molecular building block.<sup>74</sup> Chiral thioether ligands have found applications in asymmetric catalysis of allylic substitution, hydrogenation, transfer hydrogenation, hydrosilation, Michael addition, 1,4-conjugate additions, and copolymerisations.<sup>75</sup>

## 9 METALLOENZYMES

Separate sections in this series are devoted to biological and bioinorganic chemistry (*see Copper: Hemocyanin/Tyrosinase Models; Copper Proteins with Dinuclear*

*Active Sites; Copper Proteins: Oxidases; Copper Proteins with Type 1 Sites; Copper Proteins with Type 2 Sites; Copper Enzymes in Denitrification; Iron–Sulfur Models of Protein Active Sites; Iron–Sulfur Proteins; Nickel Enzymes & Cofactors; and Nickel: Models of Protein Active Sites*). However, since many metalloenzymes have been found or postulated to incorporate metal–sulfur bonding, it is appropriate that a very short summary be included here.

The structural, electronic, biological, and magnetic properties of iron–sulfur clusters in metalloproteins has been reviewed focussing particularly on  $[4\text{Fe-4S}^*]^{n+}$  ( $n = 1-3$ ) centres,<sup>76</sup> and on synthetic  $[\text{Fe}_3\text{S}_4]$  and heterometallic  $[\text{MFe}_3\text{S}_4]$  clusters.<sup>77</sup> The chemistry and properties of aconitase have been reviewed in the context of its spectroscopic properties, structure, mechanistic function, and its relationship to the iron-regulatory protein.<sup>78,79</sup>

Metallothioneins are cysteine-rich proteins capable of binding a range of metal ions, such as Zn, Cu, Cd, and Hg, via thiolate coordination. The structure of a Zn/Cd metallothionein shows a triangular array of metals, each coordinated tetrahedrally to thiolate cysteines.

The blue copper proteins azurin, plastocyanin, stellacyanin, and umecyanin incorporate Cu bound to a combination of N/thiolate/thioether ligands. An important feature of these metalloenzymes is the facile copper(II)/(I) couple that these species exhibit, which is linked to the highly strained, asymmetric coordination geometry at the metal center. The synthesis of model complexes for these so-called Type 1 copper proteins has been reviewed.<sup>80</sup>

Cytochrome  $\text{P}_{450}$  catalyzes the oxidation of external substrates and particularly the incorporation of O from  $\text{O}_2$  into C–H bonds. The active site involves an Fe-haem, with thiol ligation at an apical site from a S-donor cysteine residue being implicated in the mechanism of action. A short review of synthetic models for the active site of cytochrome  $\text{P}_{450}$  has appeared and discusses two kinds of iron porphyrins each with an axial thiolate ligand and hydroxyl groups inside the molecular cavity. A hydrogen bond to bound dioxygen has been observed in the oxy-form of a thiolate heme model system.<sup>81</sup> The electron-transfer metalloenzyme cytochrome *c* involves methionine S-coordination.

Rubredoxins are enzymes found in anaerobic bacteria and are involved in redox reactions. They contain one Fe center bound to thiolate cysteine ligands, and are modeled by tetrahedral  $\text{Fe}^{\text{II}} [\text{Fe}(\text{SR})_4]^{2-}$  and  $\text{Fe}^{\text{III}} [\text{Fe}(\text{SR})_4]^-$  complexes.

Ferredoxins and high-potential iron proteins (HiPIPs) involve clusters of two, three, and four tetrahedral Fe centers bridged by sulfido  $\text{S}^{2-}$  donors. The coordination sphere at Fe is completed by thiolate cysteine ligands.

Nitrogenase converts  $\text{N}_2$  to  $\text{NH}_3$  in leguminous plants. Much work has been reported on the synthesis of model coordination compounds and clusters for nitrogenase. This

complicated metalloenzyme contains an FeMo cofactor consisting of  $[\text{Fe}_4\text{S}_3]$  and  $[\text{Fe}_3\text{MoS}_3]$  cubanes linked together by two  $\text{S}^{2-}$  linkages and one O- or N-donor.<sup>82</sup> In addition,  $\text{Fe}_4\text{S}_4$  cubes (so-called *P* clusters) are present and act as an electron-transfer agents.<sup>83</sup> The chemistry of Mo-sulfur complexes and clusters have been reviewed in relation to the nitrogenase FeMo cofactor.<sup>84</sup>

A range of chemical analogs of the catalytic centers of Mo and W dithiolene-containing enzymes (pterins) have been prepared.<sup>85,86</sup> In particular, the rich chemistry of multisulfur transition metal systems allows ligand redox, internal electron transfer, and intermediate redox states. Such redox flexibility may facilitate coupled proton/electron transfer and/or oxo-transfer mechanisms, which are employed by Mo and W enzymes.

Hydrogenase enzymes interconvert  $\text{H}_2$  to  $2\text{H}^+$  and involve thiolate binding at FeFe or NiFe active sites. The structure of  $[\text{NiFe}]$  hydrogenase comprises a heterobimetallic NiFe centre, with the Ni ligated by four cysteines, two of which are terminal and two of which bridge to Fe. The Fe centre is ligated further by two cyanide and one carbonyl ligands.<sup>87</sup> Activation of the enzyme is believed to involve loss of a bridging oxo-ligand and contraction of the nickel–iron separation to some 2.5–2.6 Å.<sup>88</sup> The application of hydrogenase for in vitro photoinduced  $\text{H}_2$  evolution has been discussed.<sup>89</sup> A range of structural models for  $[\text{NiFe}]$  hydrogenase has been prepared,<sup>90</sup> and the reversible reduction of protons to dihydrogen in models for hydrogenase has been the subject of a recent review.<sup>91</sup>

The X-ray structure of methyl-coenzyme M reductase shows an octahedral  $\text{Ni}^{\text{II}}$  ion bound in a tetrapyrrole hydrocorphin ring and the oxygen from a glutamine residue at the fifth site. The sixth site is occupied by a thiol group of coenzyme M in the methyl-coenzyme M reductase<sub>ox1-silent</sub> structure and a sulfonate oxygen of coenzyme M in the methyl-coenzyme M reductase<sub>silent</sub> structure.<sup>92</sup>

The active site of carbon monoxide dehydrogenase has been shown to contain an asymmetric  $[\text{Ni-4Fe-5S}]$  cluster.<sup>93</sup> There have been two recent independent reports of X-ray structures for the bifunctional enzyme carbon monoxide dehydrogenase/acetyl-coenzyme A synthase. In both structures,  $\text{Ni}^{\text{II}}$  is also bound in the acetyl-coenzyme A synthase within a  $\text{N}_2\text{S}_2$  environment originating from amide N- and thiolate S-donors. The latter donors bridge to either a Cu, Zn, or Ni, which in turn is connected to a  $4\text{Fe4S}$  cluster.<sup>94,95</sup>

Zinc fingers are protein DNA-binding motifs have a finger structure, which is held together by  $\text{Zn}^{\text{II}}$  chelated by four cysteine S-donors. The binding and selectivity of Zn in proteins has been the subject of a short review.<sup>96</sup>

Compounds with S-centers such as sodium diethyldithiocarbamate and sodium thiosulfate have found use as protecting groups when used in combination with cis-platin in order to limit the toxicity associated with this

anticancer drug. The mode of action remains a subject of debate.<sup>97</sup>

## Abbreviations

bipyO<sub>2</sub> = 2,2'-bipyridyl *N,N'*-dioxide; 12-crown-4 = 1,4,7,10-tetraoxacyclododecane; 15-crown-5 = 1,4,7,10,13-penta-oxacyclododecane; 18-crown-6 = 1,4,7,10,13,16-hexa-oxacyclododecane; dbm = Dibenzoylmethane; diglyme = Bis(2-methoxyethyl)ether; dipic = 2,6-pyridinedicarboxylate; dme = 1,2-dimethoxyethane; dmi = 1,3-dimethyl-2-imidazolidione; DMP = 2,6-dimethyl-4-pyrone; DOTA = 1,4,7,10-tetraaza-cyclododecane-*N,N',N'',N'''*-tetraacetate; dpm = Dipivaloylmethane (= tmhd); dmpu = Dimethylpropylene urea; DTPA = Diethylenetriaminepentaacetate; DTPA-BMA = Dimethylamide of diethylenetriaminepentaacetic acid; EO2 = Diethylene glycol; EO3 = Triethylene glycol; EO4 = Tetraethylene glycol; EO5 = Pentaethylene glycol; facam = 3-trifluoroacetyl-d-camphor; fod = 2,2-dimethyl-6,6,7,7,8,8,8-heptafluorooctane-2,4-dione; hfac = 1,1,1,5,5,5-hexafluoropentane-2,4-dionate; Hhfp = Hexafluoroisopropanol; naph = 1,8-naphthyridine; pc = Phthalocyaninato; pmdien = *N,N,N',N'',N'''*-pentamethyldiethylene-triamine; pmhd = 1-phenyl-5-methylhexane-1,3-dionate; pu = Tetrahydro-2-pyrimidone; pyO = Pyridine *N*-oxide; terpy = 2,2':6',2''-terpyridyl; tetraglyme = Me(OCH<sub>2</sub>CH<sub>2</sub>)<sub>4</sub> OMe; tmen = *N,N,N',N'*-tetramethylethane-1,2-diamine; tmhd = 2,2,6,6-tetramethylheptane-3,5-dionate; tmu = -Tetramethylurea; Tp = Tris(pyrazolyl)borate; Tp<sup>Bur,Me</sup> = Hydrotris(3-*t*-butyl-5-methylpyrazolyl)borate; Tp<sup>Me2</sup> = Tris(3,5-dimethylpyrazolyl)borate; tpa = Tris[(2-pyridyl)methyl]amine; tpza = Tris[(2-pyrazinyl)methyl]amine; tptz = 1,3,5-tri(2-pyridyl)-2,4,6-triazine; ttfa = Thenoyltrifluoroacetato.

## 1 INTRODUCTION

These elements are generally grouped together in group 3 of the Periodic Table.<sup>1–10</sup> Scandium has considerably smaller atomic and ionic radii than the other metals and significantly different chemical properties, so it is treated separately in this article; the *Lanthanide Contraction* (see *Lanthanide Contraction*) means, however, that the later lanthanides are of similar size to yttrium, to which they bear a close chemical resemblance, and are thus often grouped together as the *Rare Earth Elements* (see *Rare Earth Elements*). The lanthanides resemble the group II metals, rather than the transition metals, in many respects – they have similar reactivities to Mg; the bonding in their complexes is essentially ionic in nature; coordination numbers are generally driven by steric considerations (and are usually high); most of the chemistry is in one oxidation state (+3). There is essentially no low oxidation-state organometallic chemistry, and they are not involved in multiple bonds, so there are no species like UO<sub>2</sub><sup>2+</sup> or MnO<sub>4</sub><sup>–</sup>. On the other hand, because of the gradual filling of the 4f subshell across the series, there are nuances in lanthanide chemistry owing to the gradual change in ionic radius – the partly filled 4f subshell leads most ions to be paramagnetic, and sometimes have visible colors; certain lanthanides (Ce, Eu, Sm, Yb in particular) have a significant chemistry in more than one oxidation state; and the complexes exhibit an exceptionally wide range in coordination numbers, often with subtle changes on passing from one lanthanide to another.

Lanthanide chemistry has its beginnings in Scandinavia.<sup>3,11</sup> In 1794, Johann Gadolin succeeded in obtaining an ‘earth’ (oxide) from a black mineral subsequently known as gadolinite, naming the earth yttria. Soon afterwards, M. H. Klaproth, J. J. Berzelius, and W. Hisinger obtained ceria, another earth, from cerite, but it was not until 1839–1843 that the Swede C. G. Mosander first separated these earths into their component oxides; thus ceria was resolved into the oxides of cerium and lanthanum and a mixed oxide ‘didymia’ (a mixture of the oxides of the metals from Pr through Gd), and likewise ‘yttria’ was separated into erbia, terbia, and yttria (though some 40 years later, the first two names were to be reversed!). Spectroscopic analysis aided the identification of further elements but also complicated matters with the erroneous identification of mixtures as over 70 ‘new’ elements. With the report of lutetium in 1907 by Urbain and von Welsbach, all the stable lanthanide elements had been discovered (von Welsbach’s alternative name of cassiopeium did not finally pass out of use until the 1950s), but Moseley showed (1913) the existence of an undiscovered element between Nd and Sm, leading to futile searches for the missing element. Counterclaims by both American and Italian researchers for element 61 (‘illinium’, ‘florentium’) were made in 1926. It was subsequently realized that element 61 would not have any stable isotopes and it was not until 1947 that it was identified in uranium fission products (and later named promethium).

Useful sources of information on these elements and their compounds include the 'Gmelin Handbook',<sup>1</sup> with extensive up-to-date coverage, and regular comprehensive reviews in the 'Handbook on the Physics and Chemistry of the Rare Earths'.<sup>2</sup> General accounts of the elements, their inorganic chemistry,<sup>3</sup> and coordination chemistry exist,<sup>4,5</sup> the latter being the most up-to-date. There are also recent monographs,<sup>6–8</sup> and compilations of in-depth and informed articles on different aspects of lanthanide chemistry and spectroscopy.<sup>9,10</sup>

When Mendeleev first published his Periodic Table in 1869, of these elements he included only lanthanum, cerium, didymium (now known to have been a mixture of Pr and Nd), another mixture in the form of erbia, and yttrium; unreliable information about atomic mass made correct positioning of these elements in the table difficult. Subsequently, it was not until the work of Bohr and of Moseley that it was known precisely how many of these elements there were. Most current versions of the Periodic Table place lanthanum under scandium and yttrium in group 3, though study of the periodic properties shows that lutetium bears a more compelling resemblance to Sc and Y, so that it has been cogently argued that these metals should appear in the same group, with lutetium preceded by the sequence La through Yb.<sup>11</sup>

In the traditional view, lanthanum is classed as a transition element; cerium, which has a 4f electron, is considered to be the first lanthanide, rather than lanthanum, which does not possess an electron in a 4f orbital (Table 1).

## 2 SCANDIUM

There are comprehensive accounts, covering the literature through 2002,<sup>3–5,12,13</sup> of the chemistry of scandium.

References to it frequently occur in the context of the chemistry of the 4f metals.

In 1869, Mendeleev predicted the existence and certain properties of an element with atomic mass 45, terming it 'ekaboron'; within a decade, the Swede L. F. Nilsson and Frenchman P. T. Cleve independently isolated scandium oxide, subsequently preparing various other compounds. There are few ores where scandium is the main element (e.g. thortveitite, a silicate,  $\text{Sc}_2\text{Si}_2\text{O}_7$ , and sterite,  $\text{ScPO}_4 \cdot 2\text{H}_2\text{O}$ ) so that it is mainly obtained as a by-product from uranium extraction.

Scandium, a soft and silvery metal, was first isolated (1937) electrolytically, but it is generally obtained metal-thermally, typically by reduction of the trifluoride with calcium. It is electropositive, tarnishing rapidly in air and reacting with water. It forms a wide range of binary compounds.

The ionic radius of  $\text{Sc}^{3+}$  is, at 0.745 Å (for six coordination) the largest of the 3d metals, so that high coordination numbers are frequently met with in its chemistry; examples between three and nine are known.

### 2.1 Binary Compounds of Scandium

#### 2.1.1 Halides

All four scandium(III) halides are known, all but the fluoride ( $\text{WO}_3$  structure) having the  $\text{FeCl}_3$  structure. They can be obtained as white solids directly from the elements and in some cases by dehydration of the hydrated salts, as well as by thermal decomposition of  $(\text{NH}_4)_3\text{ScX}_6$  ( $\text{X} = \text{Cl}, \text{Br}$ ), a method also used for the lanthanides. Gas-phase studies have identified isolated planar  $\text{ScF}_3$  molecules at 1750 K;  $\text{ScCl}_3$  molecules with a very slight pyramidal distortion; and both monomers and dimers in  $\text{ScI}_3$  vapour at 1050 K.

**Table 1** Properties of scandium, yttrium, and the lanthanides

| Element | Electronic configuration                          | Mp; bp (K)  | Atomic radius (Å) | $E(\text{M}/\text{M}^{3+})$ (V) | EC $\text{M}^{3+}$         | Ionic radius (Å) | Ground state        | Magnetic moment ( $\mu_B$ ) | Color          |

Scandium forms a number of well-defined lower halides,<sup>14</sup> especially chlorides. These are synthesized by high-temperature reaction of Sc with  $\text{ScCl}_3$ . Phases synthesized and characterized by diffraction methods are  $\text{ScCl}$ ,  $\text{Sc}_2\text{Cl}_3$  ('mouse fur'),  $\text{Sc}_5\text{Cl}_8$ ,  $\text{Sc}_7\text{Cl}_{10}$ , and  $\text{Sc}_7\text{Cl}_{12}$ . They typically have chain structures with metal–metal bonding and octahedral clusters of scandiums (Figure 1).  $\text{ScCl}$  is isostructural with  $\text{ZrBr}$ ,  $\text{Sc}_5\text{Cl}_8$  contains infinite chains of  $\text{Sc}_6$  octahedra sharing trans edges, while  $\text{Sc}_7\text{Cl}_{10}$  has two parallel chains of octahedra

sharing a common edge.  $\text{Sc}_7\text{Cl}_{12}$  is regarded as made of  $\text{Sc}_6\text{Cl}_{12}$  octahedra with isolated scandium atoms in octahedral interstices.  $\text{Sc}_2\text{Br}_3$  is also known.

### 2.1.2 Other Binary Compounds

Scandium oxide is a refractory white solid (mp 3100 °C) formed on ignition of either the metal or appropriate compounds such as the nitrate, sulfate, and hydroxide. It has amphoteric tendencies denoted by its solubility in excess alkali from which compounds like  $\text{K}_3[\text{Sc}(\text{OH})_6]$ , containing octahedrally coordinated scandium, have been isolated. In the solid state it has six-coordinate scandium in the  $\text{Mn}_2\text{O}_3$  structure.

Other significant binary compounds include the fcc dihydride  $\text{ScH}_2$ ; unlike most of the lanthanides, scandium does not form a trihydride. This compound is conducting and is probably a scandium(III) compound of the type  $\text{Sc}^{3+}(\text{H}^-)_2(\text{e}^-)$ . The carbide  $\text{ScC}$  is cubic (NaCl structure) and other carbides  $\text{Sc}_3\text{C}$ ,  $\text{Sc}_2\text{C}$ ,  $\text{Sc}_4\text{C}_3$ ,  $\text{Sc}_{13}\text{C}_{10}$ , and  $\text{Sc}_{15}\text{C}_{19}$  are reported. Fullerene complexes (see **Carbon: Fullerenes**) have been made: laser vaporization of scandium oxide–graphite mixtures followed by extraction of the resulting soot gives scandium–fullerene clusters, identified by MS to contain 1–3 scandiums, particularly paramagnetic  $\text{Sc}_n@\text{C}_{82}$  ( $n = 1, 3$ ). The three pnictides  $\text{ScQ}$  ( $\text{Q} = \text{N}, \text{P}, \text{As}$ ) exist with the nitride in particular being very high-melting (2600 °C), while there are two borides,  $\text{ScB}_2$  and  $\text{ScB}_{12}$ .

## 2.2 The Aqua Ion and Hydrated Salts<sup>15</sup>

Although there was no real evidence for the coordination number of scandium in aqueous solution, it was been generally assumed for many years that the scandium aqua ion was  $[\text{Sc}(\text{H}_2\text{O})_6]^{3+}$ , probably by analogy with the ions of the succeeding transition metals, all of which form  $[\text{M}(\text{H}_2\text{O})_6]^{3+}$  ( $\text{M} = \text{Ti}–\text{Co}$ ). Against this was the fact that  $\text{Sc}^{3+}$  has an ionic radius much larger than that of the succeeding 3d metals (0.745 Å in six-coordination), intermediate between  $\text{Ti}^{3+}$  (0.670 Å) and the lanthanides ( $\text{La}^{3+} = 1.032$  Å;  $\text{Lu}^{3+} = 0.861$  Å). Since the lanthanides form  $[\text{Ln}(\text{H}_2\text{O})_9]^{3+}$  and  $[\text{Ln}(\text{H}_2\text{O})_8]^{3+}$  aqua ions, a coordination number intermediate between 6 and 8 could have been expected for scandium on steric grounds. Study of the Raman spectra of glasses of  $\text{ScCl}_3$  and  $\text{Sc}(\text{ClO}_4)_3$  led to the suggestion that the aqua ion was not a hexaaqua species. X-ray diffraction data<sup>16</sup> from scandium perchlorate solutions gave a sharp peak (suggesting that the Sc–O distances were all very similar) having a Sc–O distance of 2.180(7) Å with a coordination number of 7.4(4). X-ray absorption fine structure (XAFS) data from scandium triflate solutions also indicate a Sc–O distance of 2.18(2) Å, but no coordination number could be unambiguously obtained from the XAFS measurements. This Sc–O distance of 2.18 Å, nearly 0.1 Å longer than that found for six-coordination, fits

**Figure 1** (a) The anionic polymetal chain in  $\text{Sc}_5\text{Cl}_8$ . (b) The structure of  $\text{Sc}_7\text{Cl}_{10}$  viewed almost along the chain axis. (Reprinted with permission from F.J. DiSalvo, J.V. Waszczak, W.M. Walsh, L.W. Rupp, and J.D. Corbett, *Inorg. Chem.*, 1985, **24**, 4624. © 1985 American Chemical Society)

well with the Sc-water distances found in the seven-coordinate  $[\text{Sc}(\text{H}_2\text{O})_7]^{3+}$  ions in the solid state. Considering all the data, it seems most likely that the predominant species present in rather acidic aqueous solution is a pentagonal bipyramidal  $[\text{Sc}(\text{H}_2\text{O})_7]^{3+}$  ion, with an average Sc–O distance around 2.18 Å. Study of the scandium aqua ion is handicapped by its ready hydrolysis and ability to complex with anions like chloride, nitrate, and even perchlorate.  $^{45}\text{Sc}$  NMR studies on aqueous solutions of the chloride, nitrate, and formate were been interpreted in terms of the presence of both the aqua ion and mixed aqua/hydroxy species.

Among hydrated salts, scandium forms perchlorates  $\text{Sc}(\text{ClO}_4)_3 \cdot n\text{H}_2\text{O}$  ( $n = 6, 7$ ); the hexahydrate is isostructural with the lanthanide analogues, thus containing octahedral  $[\text{Sc}(\text{H}_2\text{O})_6]^{3+}$  ions. The very soluble scandium triflate is isostructural with the lanthanide analogues  $\text{Ln}(\text{O}_3\text{SCF}_3)_3 \cdot 9\text{H}_2\text{O}$ , though there is evidence that the cation present is actually  $[\text{Sc}(\text{H}_2\text{O})_8]^{3+}$ , rather than the nonaqua species. When scandium halides (except the fluoride) are recrystallised from slightly acidified aqueous solution (to prevent the hydrolysis that could otherwise result in the hydroxy-bridged dimers discussed below), hydrated salts  $\text{ScX}_3 \cdot 7\text{H}_2\text{O}$  ( $\text{X} = \text{Cl}, \text{Br}$ ) and  $\text{ScI}_3 \cdot 8\text{H}_2\text{O}$  are obtained. X-ray diffraction studies<sup>17</sup> show them all to contain  $[\text{Sc}(\text{H}_2\text{O})_7]^{3+}$  ions; in the chloride and iodide, the coordination geometry is essentially pentagonal bipyramidal, whilst in the iodide there is a substantial distortion (in view of the tendency of many of the hydrated lanthanide halides to contain coordinated halide ions, the chlorides in particular, the absence of halide from the coordination sphere of scandium in these compounds is remarkable). Reaction of refluxing aqueous  $\text{HC}(\text{SO}_2\text{CF}_3)_3$  with scandium oxide yields the triflate salt  $[\text{Sc}(\text{H}_2\text{O})_7] (\text{C}(\text{SO}_2\text{CF}_3)_3)_3$ . Though complicated by disorder, the structure shows two scandium-containing sites, with Sc–O distances falling in the range 2.113 (13)–2.222 (10) Å, averaging 2.17 Å. In contrast, the ytterbium analogue contains eight-coordinate  $[\text{Yb}(\text{H}_2\text{O})_8]^{3+}$  ions.

Overall, then, the existence of the three scandium-containing ions  $[\text{Sc}(\text{H}_2\text{O})_x]^{3+}$  ( $x = 6, 7, 8$ ) in five different solid salts indicates that in itself X-ray diffraction data on solids cannot be relied upon to indicate the coordination number in aqueous solution. Ultimately, it is the solubility of a particular salt that determines which compound crystallises out from aqueous solution.

Other hydrated salts include  $\text{Sc}_2(\text{C}_2\text{O}_4)_3 \cdot 6\text{H}_2\text{O}$ ,  $\text{Sc}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$ , and  $\text{Sc}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{O}$ ; the structure of the oxalate shows approximately dodecahedral coordination of scandium by two water molecules and six oxygens from bridging oxalates. The oxalate is, unlike lanthanide oxalates, slightly soluble in water and also dissolves in excess oxalate as  $\text{Sc}(\text{C}_2\text{O}_4)_2^-$ . No structural data are available for the nitrate, although it should be noted that eight-coordinate  $\text{Sc}(\text{NO}_3)_3(\text{H}_2\text{O})_2$  and nine-coordinate  $\text{Sc}(\text{NO}_3)_3(\text{H}_2\text{O})_3$  molecules are present in crown ether

complexes, while the sulfate  $\text{Sc}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{O}$  has six-coordinate scandium. Both the nitrate and sulfate dehydrate on heating above 100 °C; at higher temperatures they change to the oxide. Structures are known of two other salts where water shares the coordination sphere of scandium with anions. Freshly precipitated  $\text{Sc}(\text{OH})_3$  reacts with picric acid (HPic) forming a 1:1 adduct with picric acid, *trans*- $[\text{Sc}(\text{H}_2\text{O})_4(\text{pic})_2](\text{pic})(\text{HPic}) \cdot 8.2 \text{H}_2\text{O}$ ; scandium is present as part of a six-coordinate cation. In contrast to the benzenesulfonate, the *p*-toluenesulfonate salt  $\text{Sc}(\text{tosylate})_3 \cdot 6\text{H}_2\text{O}$  has coordinated anions in six-coordinate  $[\text{Sc}(\text{H}_2\text{O})_4(\text{tosylate})_2]^+$  ions (the tosylates of the heavier lanthanides have six bound water molecules and two coordinated tosylates in eight-coordinate cations).

An important dimeric species is the  $[(\text{H}_2\text{O})_5\text{Sc}(\text{OH})_2\text{Sc}(\text{H}_2\text{O})_5]^{4+}$  ion (Figure 2), a cationic species with two hydroxy bridges, with approximately pentagonal bipyramidal coordination of scandium. It has been characterized as a benzene sulfonate salt,<sup>18</sup> and also as chlorides and bromides  $[(\text{H}_2\text{O})_5\text{Sc}(\mu\text{-OH})_2\text{Sc}(\text{H}_2\text{O})_5] \text{X}_4 \cdot 2\text{H}_2\text{O}$  ( $\text{X} = \text{Cl}, \text{Br}$ ). The Sc–OH<sub>2</sub> and the Sc–OH bond lengths are similar in all three of these dimeric cations. These  $[(\text{H}_2\text{O})_5\text{Sc}(\mu\text{-OH})_2\text{Sc}(\text{H}_2\text{O})_5]^{4+}$  ions are significant in that they are believed to be formed in the first stage of the hydrolysis of the scandium aqua ion, and the coordination geometry involving scandium bound to seven water molecules and hydroxide ions can clearly derive from a  $[\text{Sc}(\text{H}_2\text{O})_7]^{3+}$  ion.

Among the carboxylates, scandium formate has a 2-D polymeric structure, whilst in the acetate, chains of  $\text{Sc}^{3+}$  ions are bridged by acetate groups (Figure 3) with essentially octahedral coordination of scandium. Similar bridging is found in the chloroacetate, where the six-coordination is in contrast with the nine-coordinate trimeric structure adopted by the heavier lanthanide ions. Scandium propynoate has

**Figure 2** Structure of the dimeric cation  $[(\text{H}_2\text{O})_5\text{Sc}(\text{OH})_2\text{Sc}(\text{H}_2\text{O})_5]^{4+}$

Figure 3 Chain structure in scandium acetate

an unusual three-dimensional polymeric structure (featuring six-coordinate scandium) that undergoes polymerization on  $\gamma$ -irradiation (probably with formation of a poly(propynoate)).<sup>19</sup>

### 2.3 Complexes<sup>4,5</sup>

A range of O-donor ligands (e.g. pyO, Me<sub>2</sub>SO, HMPA, R<sub>3</sub>PO) forms complexes with scandium, with two main series, ScL<sub>3</sub>X<sub>3</sub> (where X is a coordinating anion such as chloride) and ScL<sub>6</sub>X<sub>3</sub> (with anions such as perchlorate). With nitrate, higher coordination numbers are possible (because of the small 'bite' angle of bidentate nitrate).

A large number of complexes of phosphine and arsine oxides have been examined. Sc(OTf)<sub>3</sub>(Ph<sub>3</sub>PO)<sub>4</sub> has the structure *trans*-[Sc(OTf)<sub>2</sub>(Ph<sub>3</sub>PO)<sub>4</sub>] OTf, featuring octahedrally coordinated scandium (monodentate triflates), whilst [Sc(NO<sub>3</sub>)<sub>3</sub>(Ph<sub>3</sub>PO)<sub>2</sub>] is eight-coordinate with symmetrically bidentate nitrates. Both Sc(NO<sub>3</sub>)<sub>3</sub>(Ph<sub>2</sub>MePO)<sub>3</sub> and Sc(NO<sub>3</sub>)<sub>3</sub>(Ph<sub>2</sub>MePO)<sub>4</sub> exist; the latter is [Sc(NO<sub>3</sub>)<sub>2</sub>(Ph<sub>2</sub>MePO)<sub>4</sub>](NO<sub>3</sub>) (bidentate nitrates). With Me<sub>3</sub>PO, [Sc(Me<sub>3</sub>PO)<sub>6</sub>](NO<sub>3</sub>)<sub>3</sub> is formed; similarly [Sc(Me<sub>3</sub>AsO)<sub>6</sub>](NO<sub>3</sub>)<sub>3</sub> has octahedrally coordinated scandium. Sc(NO<sub>3</sub>)<sub>3</sub>(Ph<sub>3</sub>AsO)<sub>3</sub> is seven-coordinate [Sc(NO<sub>3</sub>)<sub>2</sub>(Ph<sub>3</sub>AsO)<sub>3</sub>](NO<sub>3</sub>). Among halide complexes, *trans*-[ScBr<sub>2</sub>(Ph<sub>3</sub>PO)<sub>4</sub>]Br, *trans*-[ScCl<sub>2</sub>(Ph<sub>3</sub>AsO)<sub>4</sub>]Cl and [Sc(Me<sub>3</sub>AsO)<sub>6</sub>]Br<sub>3</sub> have all had structures confirmed by X-ray diffraction. Six-coordinate is likewise found in *trans*-[Sc(HMPA)<sub>4</sub>(CF<sub>3</sub>SO<sub>3</sub>)<sub>2</sub>]CF<sub>3</sub>SO<sub>3</sub> and the tetrahydro-2-pyrimidone complex [Sc(pu)<sub>6</sub>](CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, the latter unexpectedly having trigonal antiprismatic coordination of scandium, possibly partly induced by side-on interactions between pairs of pu ligands. Various complexes of *N*-oxide ligands ScL<sub>6</sub>(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> (L = pyridine *N*-oxide, 2-picoline *N*-oxide, 3-picoline *N*-oxide, 4-picoline *N*-oxide) have been described, and all presumably contain octahedrally coordinated scandium, confirmed in [ScCl<sub>3</sub>(dme)(MeCN)] and [ScCl<sub>3</sub>(diglyme)].

(NO<sup>+</sup>)<sub>2</sub> [Sc(NO<sub>3</sub>)<sub>5</sub>]<sup>2-</sup> contains a nine-coordinate pentakis(nitrato)scandate ion, one nitrate being monodentate, but in Rb<sub>2</sub> [Sc(NO<sub>3</sub>)<sub>5</sub>] there are three bidentate and two monodentate nitrates, resulting in eight-coordinate scandium. These contrast with the lanthanide analogs which are ten-coordinate

(the lanthanides also form 12-coordinate hexa(nitrato) complexes, see Section 3.7.7).

There are a number of complexes with diketonates, all probably octahedral like Sc(acac)<sub>3</sub> (X-ray); Sc(tropolonate)<sub>3</sub> also has six-coordinate scandium but eight-coordinate also exists in HSc(tropolonate)<sub>4</sub> and probably in similar Sc(diketonate)<sub>4</sub><sup>-</sup> species. A number of crown ether complexes<sup>20</sup> like Sc(NO<sub>3</sub>)<sub>3</sub>(H<sub>2</sub>O)<sub>2</sub>·crown (crown = 15-crown-5, benzo-15-crown-5) do not involve direct crown ether–scandium bonding; instead they have hydrated scandium nitrate molecules linked to the crown ether by hydrogen bonds to the ether oxygens. However, reaction of ScCl<sub>3</sub> with halogen-extractor SbCl<sub>5</sub> and 18-crown-6 in acetonitrile gives [ScCl<sub>2</sub>(18-crown-6)](SbCl<sub>6</sub>), in which the scandium is bound (Figure 4) to five ether oxygens and two chlorines in roughly pentagonal bipyramidal coordination.

Other [ScCl<sub>2</sub>(crown)]<sup>+</sup> [SbCl<sub>6</sub>]<sup>-</sup> species (crown = 15-crown-5, benzo-15-crown-5, and dibenzo-18-crown-6) complexes have been isolated, all believed to have a pentagonal bipyramidal coordination geometry, confirmed crystallographically for the benzo-15-crown-5 complex. Reaction of ScCl<sub>3</sub>(thf)<sub>3</sub> and 1 mol of SbCl<sub>5</sub> with 1 mol of a larger crown ether yields the complexes [ScCl<sub>2</sub>(dibenzo-24-crown-8)(H<sub>2</sub>O)]<sup>+</sup> [SbCl<sub>6</sub>]<sup>-</sup>·2 MeCN and [ScCl<sub>2</sub>(dibenzo-30-crown-10)(H<sub>2</sub>O)<sub>2</sub>]<sup>+</sup> [SbCl<sub>6</sub>]<sup>-</sup>·MeCN·H<sub>2</sub>O. The cavity in the smaller tetradentate 12-crown-4 ring is too small for a [ScCl<sub>2</sub>]<sup>+</sup> ion to fit, so [ScCl<sub>2</sub>(12-crown-4)(MeCN)]<sup>+</sup> [SbCl<sub>6</sub>]<sup>-</sup> is believed to have an 'extra-cavity' (half-sandwich) structure.

Use of excess SbCl<sub>5</sub> permits the extraction of further chlorides from the crown ether complexes. Thus reaction of [ScCl<sub>3</sub>(thf)<sub>3</sub>] in MeCN with 3 mols of SbCl<sub>5</sub> and dibenzo-18-crown-6 leads to the complex [ScCl(dibenzo-18-crown-6)(MeCN)]<sup>2+</sup> (SbCl<sub>6</sub><sup>-</sup>)<sub>2</sub>. If SbCl<sub>5</sub> and SbCl<sub>3</sub> are used together, [Sc(12-crown-4)<sub>2</sub>]<sup>3+</sup> (Sb<sub>2</sub>C<sub>8</sub>)(SbCl<sub>6</sub>)<sub>2</sub>(MeCN)<sub>2</sub> is obtained, with eight-coordinate Sc.

Few scandium alkoxides have been studied in detail, but monomeric three coordination is known in [(2,6-(*t*-Bu)<sub>2</sub>-4-MeC<sub>6</sub>H<sub>2</sub>O)<sub>3</sub>Sc], where the bulky ligand enforces steric

Figure 4 Seven-coordinate scandium in [ScCl<sub>2</sub>(18-crown-6)](SbCl<sub>6</sub>)

crowding. It will, however, expand its coordination sphere to form four-coordinate adducts with  $\text{Ph}_3\text{PO}$  and  $\text{thf}$ , unlike the corresponding three-coordinate silylamide.  $\text{Sc}(\text{OSi}(t\text{-Bu})_3)_3 \cdot \text{L}$  ( $\text{L} = \text{thf}$ ,  $\text{py}$ ,  $\text{NH}_3$ ) have also been prepared (the Lewis base cannot, however, be removed to afford the homoleptic siloxide; see *Homoleptic Compound*). The isopropoxide is pentanuclear  $[\text{Sc}_5\text{O}(\text{OPr}^i)_{13}]$ , similar to those formed by Y, Yb, and In, with the structure  $[\text{Sc}_5(\mu_5\text{-O})(\mu_3\text{-OPr}^i)_4(\mu_2\text{-OPr}^i)_4(\text{OPr}^i)_5]$ . Anodic oxidation of scandium in aliphatic alcohols has been used as a pathway to scandium alkoxides  $[\text{Sc}(\text{OR})_3]$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ ) and  $[\text{Sc}_5\text{O}(\text{OPr}^i)_{13}]$ . The elusive structure of the methoxide  $[\text{Sc}(\text{OMe})_3]$  is still not known; it appears not to contain an oxo ligand, and to be a polymer. Alcoholysis of  $[\text{Sc}_5\text{O}(\text{OPr}^i)_{13}]$  leads to  $[\text{Sc}(\text{OR})_3]$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ ,  $\text{Bu}^n$ ),  $[\text{Sc}_5\text{O}(\text{OBU}^s)_{13}]$  and  $[\text{Sc}_5\text{O}(\text{OPr}^i)_8(\text{OBU}^t)_5]$ .

Scandium complexes with ammonia have only been made by dry methods.<sup>21</sup> In  $(\text{NH}_4)_2[\text{Sc}(\text{NH}_3)_5\text{I}_5]$ , obtained from reaction of  $\text{NH}_4\text{I}$  and metallic scandium in a sealed tube at  $500^\circ\text{C}$ , scandium has octahedral coordination with  $\text{Sc-N} = 2.29$  (2) Å and  $\text{Sc-I} = 2.856(5) - 2.899(5)$  Å. Reaction of Sc with  $\text{NH}_4\text{Br}$  in a sealed Ta vessel gives  $[\text{Sc}(\text{NH}_3)_2\text{Br}_3]$  (isotypic with  $\text{Sc}(\text{NH}_3)_2\text{Cl}_3$ ) having isolated dimers of bromide edge-connected  $[\text{mer-Sc}(\text{NH}_3)_3\text{Br}_3]$  and  $[\text{Sc}(\text{NH}_3)_3\text{Br}_5]$  octahedra.  $[\text{Sc}(\text{NH}_3)_3\text{Br}_3]$ , isotypic with  $\text{Sc}(\text{NH}_3)_3\text{Cl}_3$ , has zigzag chains of edge-connected  $[\text{Sc}(\text{NH}_3)_3\text{Br}_5]$  octahedra as  $[\text{Sc}(\text{NH}_3)_{1/1}\text{Br}_{1/1}\text{Br}_{4/2}]$ .

Reaction of the anhydrous  $\text{ScX}_3$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ) with pyridine yields  $\text{Sc}(\text{py})_4\text{X}_3$ , which possibly have one molecule of pyridine in the lattice, as it is lost in vacuo.  $\text{Sc}(\text{py})_3(\text{NCS})_3$  also exists. Using bidentate ligands,  $\text{ScL}_2\text{X}_3$  ( $\text{L} = \text{phen}$ ,  $\text{bipy}$ ) have been made, sometimes in two forms; they are believed to be  $[\text{ScL}_2\text{X}_2]^+\text{X}^-$  and it is possible that *cis* and *trans*-isomers may exist, but there is no structural confirmation. Similar ethylenediamine complexes have been made by removal of a ligand molecule in vacuo from  $\text{Sc}(\text{en})_3\text{X}_3$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ). Of the complexes of tridentate N-donors, the best characterized is  $\text{Sc}(\text{terpy})(\text{NO}_3)_3$ , which has nine-coordinate scandium, but with one rather long  $\text{Sc-O}$  bond.

A range of porphyrins and phthalocyanines exist; syntheses often involve the high-temperature routes typical of the transition metals but recently a high-yield low-temperature route has been utilized:

The chloride can be replaced by alkoxy, alkylamide, alkyl, and cyclopentadienyl groups. Similar compounds with other porphyrins and with phthalocyanine have been made, as well as the oxo-bridged dimer  $(\text{OEP})\text{Sc}(\mu\text{-O})\text{Sc}(\text{OEP})$ .

Scandium resembles the other 3d transition metals from titanium through cobalt in forming an unusual three-coordinate silylamide,  $\text{Sc}[\text{N}(\text{SiMe}_3)_2]_3$ , but unlike them its solid-state structure is pyramidal, not planar, in which respect it resembles the lanthanides and uranium. It does not form adducts with Lewis bases, presumably on steric

grounds, the resemblance here being to the 3d metals. The less congested amide  $[\text{Sc}\{\text{N}(\text{SiHMe}_2)_2\}_3]$  forms a  $\text{thf}$  adduct  $[\text{Sc}\{\text{N}(\text{SiHMe}_2)_2\}_3(\text{thf})]$ , which has distorted tetrahedral coordination of scandium, with short solid-state  $\text{Sc} \cdots \text{Si}$  contacts (this is in contrast to 5-coordinate  $[\text{Ln}\{\text{N}(\text{SiHMe}_2)_2\}_3(\text{thf})_2]$  ( $\text{Ln} = \text{La-Lu}$ ).

Like other  $\text{M}^{3+}$  ions, scandium forms strong complexes with EDTA and DTPA. In  $\text{NH}_4[\text{Sc}(\text{EDTA})(\text{H}_2\text{O})_2] \cdot 3\text{H}_2\text{O}$ , scandium is eight-coordinate with hexadentate EDTA and two coordinated water molecules, as expected in comparison with the smaller  $\text{Fe}^{3+}$  ion (forming seven-coordinate  $[\text{Fe}(\text{EDTA})(\text{H}_2\text{O})]^-$ ) or larger  $\text{La}^{3+}$  ion (which forms nine-coordinate  $[\text{La}(\text{EDTA})(\text{H}_2\text{O})_3]^-$ ). Again, scandium is eight-coordinate in  $\text{Mn}[\text{Sc}(\text{DTPA})] \cdot 4\text{H}_2\text{O}$ , in which DTPA is octadentate but there are no coordinated water molecules, unlike the complex of the larger  $\text{Gd}^{3+}$  ion,  $[\text{Gd}(\text{DTPA})(\text{H}_2\text{O})]^{2-}$ , familiar as a magnetic resonance imaging (MRI) contrast agent (see Section 'Magnetic Resonance Imaging and MRI Agents'), also in the  $[\text{Sc}(\text{DOTA})]^-$  ion found in  $[\text{NaSc}(\text{DOTA})]_3 \cdot \text{NaOH} \cdot 18\text{H}_2\text{O}$ , where the coordination geometry is twisted square antiprismatic. These compounds nicely illustrate the tendency of  $\text{Sc}^{3+}$  to adopt coordination numbers intermediate between those of the  $\text{M}^{3+}$  ions in the first transition series and those found for the lanthanides.

The best-defined halide complexes are the hexafluoroscandates,  $\text{M}_3\text{ScF}_6$ , which clearly contain  $\text{ScF}_6^{3-}$  anions;  $\text{Na}_3\text{ScF}_6$  adopts the cryolite structure,  $\text{K}_2\text{NaScF}_6$  also has the cubic elpasolite structure, as does the high-temperature phase of  $\text{Rb}_2\text{KScF}_6$ ;  $\text{Sr}_2\text{ScF}_7$  has seven-coordinate scandium however.  $\text{KScF}_4$  has a layered structure in which scandium acquires six-coordination by edge-sharing alternate *cis*- and *trans*-corners, whilst  $(\text{enH}_2)_{0.5}\text{ScF}_4$  has corner-linked octahedral.  $\text{Ba}_2\text{ScCl}_7$  is  $\text{Ba}_2[\text{ScCl}_6]\text{Cl}$ , whilst  $\text{Na}_3\text{ScCl}_6$  again has the cryolite structure.  $\text{NaScCl}_4$  is isostructural with  $\text{NaLuCl}_4$ , the structure being made up of *cis*- edge-sharing  $\text{ScCl}_6$  octahedra.  $\text{Na}_3\text{ScBr}_6$  has the  $\text{Na}_3\text{CrCl}_6$  structure.

### 3 YTTRIUM AND THE LANTHANIDES<sup>22</sup>

The lanthanides exhibit a number of features in their chemistry that differentiate them from the d-block metals.

1. Reactivity significantly greater than the transition metals, akin to group 2 elements.
2. A wide range of coordination numbers (generally 6–12, but 2–5 are also known).
3. Coordination geometries determined by ligand steric factors rather than crystal-field effects.
4. The formation of labile 'ionic' complexes that undergo facile exchange of ligand.
5. The inability of the 4f orbitals (see *f-Orbitals*) in the  $\text{Ln}^{3+}$  ion to participate directly in bonding.<sup>23</sup> Their

spectroscopic and magnetic properties are thus largely uninfluenced by the ligand.

6. Small crystal-field splittings (*see Crystal Field Theory*) and very sharp electronic spectra in comparison with the d-block metals.
7. The preference for anionic ligands with donor atoms of rather high *Electronegativity* (e.g. O, F, *see Electronegativity*).
8. The ready formation of hydrated complexes (on account of the high hydration energy of the small  $\text{Ln}^{3+}$  ion) and this can cause uncertainty in assigning coordination numbers.
9. The insolubility of hydroxides which precipitate at neutral pH unless complexing agents are present.
10. The dominance of one (3+) oxidation state.
11. Their inability to form  $\text{Ln}=\text{O}$  or  $\text{Ln}\equiv\text{N}$  multiple bonds of the type known for many transition metals and certain actinides.
12. Unlike the transition metals, they do not form stable carbonyls, and have virtually no chemistry in the 0 oxidation state.

### 3.1 Ores and Extraction of the Metals<sup>1,3,6</sup>

In general, Y and the heavier lanthanides, Gd to Lu, are less abundant than the lighter lanthanides, La to Eu. However, there are two further complicating factors: one is that the elements with even atomic number are more abundant than those of odd atomic number, reflecting the greater stability of such nuclei. Secondly, some ores (e.g. bastnasite, monazite) are richer in the lighter metals while others (e.g. xenotime) have more of the heavier metals. The abundance of yttrium in the Earth's crust is 31 ppm while the total abundance of the lanthanides is some 180 ppm; cerium is the most abundant (66 ppm), while thulium and lutetium are the rarest (0.5 and 0.8 ppm, respectively).

Although over 150 minerals are known to contain lanthanides, the three most important (outside of China) are bastnasite ( $\text{LnFCO}_3$ ), monazite ( $\text{LnPO}_4$ ), and xenotime ( $\text{LnPO}_4$ ). The main western source of bastnasite is California, USA, with some coming from Baiyunebo (inner Mongolia) where it is present as part of an iron ore. Monazite mainly comes from China and Australia (with important contributions from Malaysia, India, and Brazil), where the monazite contains 5–10% of  $\text{ThO}_2$  (whose radioactivity presents an additional processing problem). Xenotime is likewise a phosphate containing rather more of the heavier metals and also containing thorium oxide with some  $\text{U}_3\text{O}_8$  (main exporters are Australia, China, and Malaysia). Chinese rare earth reserves amount to over 70% of the known world total. Much of this is in the form of the ionic ores from southern provinces, of which the Longnan mineral contains a remarkable quantity of yttrium oxide (over 60%). These Chinese ion-absorption ores, weathered granites with lanthanides adsorbed on to the surface of aluminum silicates, are in some cases low in cerium and

rich in the heavier lanthanides (Longnan), while the Xunwu deposits are rich in the lighter metals; the small particle size makes them easy to mine.

### 3.2 Extraction of the Lanthanides

As mined, Californian bastnasite contains around 8% lanthanide oxides. Flotation followed by dissolution of the calcite content in 10% HCl concentrates this to around 70%. The resulting concentrate is treated to oxidize  $\text{Ce}^{\text{III}}$  to  $\text{Ce}^{\text{IV}}$ , followed by reaction with hydrochloric acid to dissolve the oxides of the metals La and Pr through Gd, separating them from cerium (which is recovered as  $\text{CeO}_2$ ). Solvent extraction of the resulting solution affords the individual lanthanides (europium can be separated from the mixture by zinc reduction to  $\text{Eu}^{\text{II}}$ , followed by precipitation as  $\text{EuSO}_4$ ). Monazite is generally first treated with NaOH at 150 °C to remove phosphate as  $\text{Na}_3\text{PO}_4$ , leaving a mixture of the hydroxides of lanthanum and thorium. These can be separated either by selective precipitation of  $\text{Th}(\text{OH})_4$  while the  $\text{Ln}^{3+}$  ions remain in solution, or by selectively dissolving the lanthanides out of the hydroxide mixture. The resulting solution of  $\text{Ln}^{3+}$  ions is separated into the individual metal ions by solvent extraction.

Various other separation methods have been described, one recent one involving the use of supercritical carbon dioxide at 40 °C and 100 atm to convert the lanthanides into their carbonates, while the quadrivalent metals (e.g. Th and Ce) remain as their oxides.

For many years up to and immediately following the Second World War, isolation of the individual lanthanide compounds in a pure state was a problem that required innumerable fractional crystallizations of salts such as the bromates or magnesium double nitrates, exploiting slight solubility differences. As radioactive lanthanide isotopes are among the important fission products of uranium and because it was expected that the elements beyond plutonium would resemble the lanthanides, the development of ion-exchange chromatography was a highly important spin off from the Manhattan project and commercial separation processes based on cation exchange rapidly came into being. The later lanthanides with their smaller ionic radii conversely have the larger hydrated radii because of their greater tendency to attract water molecules. The separation relies on the use of complexing agents such as EDTA and HEDTA (hydroxyethylethylenediaminetriacetate), which form stronger complexes with the heavier lanthanides and elute them first (the original eluent was ammonium citrate).

The major disadvantage of ion exchange is that it is a slow process for large-scale separations. Solvent extraction has therefore come to be the process of choice, at least for the initial separation (up to the 99.9% purity level); it employs an automated continuous counter-current process using a two-solvent mixture, an acid ( $\text{HCl}$  or  $\text{HNO}_3$ ) aqueous phase, and an organic phase, for which tributyl phosphate or similar compound with a  $\text{P}=\text{O}$  group is the usual complexing ligand.

This process is capable of giving individual lanthanides of sufficient purity for chemical use (99.9%), but for electronic or spectroscopic use ('phosphor grade') 99.999% purity is necessary, and further ion exchange is used for final purification to these levels.<sup>24</sup>

### 3.3 Preparation and Properties of the Metals<sup>25</sup>

Most of the elements are usually made by metallothermic reduction of the trifluoride, generally with calcium in excess of 1000 °C.

The fluoride is chosen as it is both nonhygroscopic and also oxide-free. This method is not applicable to Sm, Eu, or Yb, which are only reduced to the difluorides; these metals are instead made by heating their oxides with lanthanum at 1000–1300 °C, the more volatile metal being removed by distillation at low pressure:

A third method, electrolysis of the mixed molten chlorides of the lighter lanthanides, is used to make the lanthanide mixture known as mischmetal. For some research applications, ultrapure metals are needed as even small quantities of light nonmetals such as carbon and hydrogen can have a marked effect on the properties of the metal. Thus if the  $\text{LnF}_3\text{--Ca}$  method is used the molten fluoride has to be treated with HF to ensure the absence of the oxyfluoride, while the calcium is twice redistilled under an ultrapure argon atmosphere before use. Further purification of the lanthanide can be achieved by methods including vacuum remelting, zone melting, and distillation.

These elements are silvery white reactive metals. The reactivity order is europium followed by lanthanum through lutetium, the exception being ytterbium, placed between Sm and Gd. Yttrium resembles terbium and dysprosium. Europium is quickly oxidized by air and the powdered metal can be pyrophoric; it reacts with water like calcium. Lighter lanthanides are oxidized readily at room temperature, especially in moist air, but the metals in the second half of the series tend to be fairly stable in dry air. All the metals dissolve rapidly in dilute acid and react slowly with the halogens at room temperature, rapidly on warming. Similar reactions occur with other nonmetals (S, C, N<sub>2</sub>, Si, B, H<sub>2</sub>) on heating. In their reactivity the metals resemble the alkaline earth metals; in the case of Eu and Yb the resemblance extends to forming dark blue solutions in liquid ammonia. The physical properties of the lanthanide metals follow a smooth pattern, with the exception of the metals with a tendency to divalency. The atomic radii of Eu and Yb are ca. 0.2 Å greater (and the densities correspondingly lower) than the other metals;

samarium, ytterbium, and europium are considerably more volatile than the other lanthanides, implying that while most lanthanide metals can be represented as  $\text{Ln}^{3+}(\text{e}^-)_3$ , Eu and Yb should be regarded as  $\text{Ln}^{2+}(\text{e}^-)_2$ .

The lanthanides form a wide range of alloys, several of considerable importance.  $\text{LaNi}_5$  readily absorbs hydrogen gas up to a composition  $\text{LaNi}_5\text{H}_6$  and has been extensively studied for its potential for hydrogen removal and storage (as H<sub>2</sub> is desorbed on heating to about 140 °C), rechargeable batteries (as used in notebook PCs), electrode and fuel-cell materials, and in catalytic hydrogenation. Samarium–cobalt alloys have been widely used as  $\text{SmCo}_5$  and  $\text{Sm}_2\text{Co}_{17}$  in permanent magnets. A ferrocenium alloy containing 25% iron and 75% mixed light lanthanides, mainly cerium (mischmetal), is used to make lighter flints; another use of mischmetal is for deoxidation and desulfurization of steels.

### 3.4 Oxidation States and Coordination Numbers<sup>10</sup>

The adoption of the (+3) oxidation state by the lanthanides in most of their chemistry is a consequence of the balance of a number of factors,<sup>6,26,27</sup> although many divalent and tetravalent compounds also exist. Nevertheless, in aqueous solution, only the lanthanide(III) ions are stable;  $\text{Ce}^{4+}$  is metastable whilst  $\text{Eu}^{2+}$  has a life of a few hours.

The ionic radius of the smallest lanthanide(III) ion,  $\text{Lu}^{\text{III}}$  is 0.861 Å (for six coordination), considerably greater than that of scandium and the 3d metals (corresponding values for lanthanum and yttrium are 1.032 and 0.900 Å, respectively). Purely on steric grounds, high coordination numbers would therefore be expected for  $\text{Ln}^{3+}$ , and in fact a range of values between 3 and 12 is known. The observed geometries are discussed in more detail in Section Magnetic Resonance Imaging and MRI Agents.

The lack of directional character of the essentially ionic bonding is a result of crystal-field effects being absent. The decreasing size of the lanthanide atoms and ions across the series, the *Lanthanide Contraction* (see *Lanthanide Contraction*), is due to the contraction of the (5s<sup>2</sup>5p<sup>6</sup>) configuration due to their penetration inside the 4f orbitals (a similar contraction is noted for the transition metals, although for a different reason).<sup>28</sup> Consequently a decrease in coordination number in a series of related compounds is often observed.

### 3.5 Magnetic and Spectroscopic Properties of the $\text{Ln}^{3+}$ Ions<sup>29,30</sup>

These may be accounted for in terms of the Russell–Saunders coupling scheme in which the electron spins are coupled together separately from the coupling of the orbital angular momenta of the electrons and the orbital moment is unquenched. The ground state for a given lanthanide ion is unaffected by the ligands (and thus crystal-field splittings are weak) because of the shielding of the 4f electrons by the

filled 5s and 5p orbitals. The strength of spin–orbit coupling means that the ground state is well separated from excited states, except for  $\text{Sm}^{3+}$  and  $\text{Eu}^{3+}$ , where contributions from low-lying paramagnetic excited states contribute to the magnetic moment. Thus, if the magnetic properties of the  $\text{Eu}^{3+}$  ion were solely determined by the  $^7\text{F}_0$  ground state, its compounds would be diamagnetic, whereas contributions from thermally accessible levels such as  $^7\text{F}_1$  and  $^7\text{F}_2$  lead to the observed magnetic moments in the region of  $3.5 \mu_{\text{B}}$ . The magnetic moments in the second half of the series are greater than those in the first half, as  $J = L + S$  for a shell greater than half-filled and  $J = L - S$  for a less than half-filled shell. (Table 1 lists the magnetic moments for the tripositive lanthanide ions.) The magnetic moment of the  $\text{Ln}^{3+}$  ions are essentially independent of environment, from the practical viewpoint of the coordination chemist measuring bulk powder samples at around room temperature. The moments are given by the equation

$$\mu_{\text{eff}} = g_J \sqrt{J(J+1)} \quad (4)$$

**Figure 5** (a) Excitation spectrum at 77 K of  $\text{Eu}(\text{NO}_3)_3 \cdot 15\text{-crown-5}$  ( $\lambda_{\text{anal}} = 618 \text{ nm}$ ) (b) Fluorescence spectrum at 77 K ( $\lambda_{\text{exc}} = 397.7 \text{ nm}$ ). (Reprinted with permission from J.-C.G. Bunzli, B. Klein, G. Chapuis, and K.J. Schenk, *Inorg. Chem.*, 1982, **21**, 808. © 1982 American Chemical Society)

where the Landé  $g$  factor is defined by

$$g_J = \frac{[S(S+1) - L(L+1) + 3J(J+1)]}{2J(J+1)} \quad (5)$$

The electronic spectra of lanthanide compounds resemble those of the free ions, in contrast to the norm in transition metal chemistry; the crystal-field (CF) splittings can be treated as a perturbation on the unsplit  $^{2S+1}L_J$  levels. A further consequence of the weak CF splittings is the sharpness of the f–f transitions. The spectrum of the complex  $\text{Eu}(\text{NO}_3)_3(15\text{-crown-5})$  shown in (Figure 5) displays this.

Certain transitions in the electronic spectra of some tripositive lanthanide ions (notably Nd, Ho, Er) exhibit ‘hypersensitivity’ to the environment, which can sometimes be used to indicate geometry, as in the case of the neodymium(III) aqua ion shown in Figure 6.

Study of the intensity and splitting pattern of certain transitions in the fluorescence spectra of compounds of  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  in particular can give a good deal of information about the environment of the lanthanide ion.<sup>31,32</sup> The  $^7\text{F}_0$  ground state is unsplit, so that transitions to it give straightforward information about the excited state. Thus, since the  $^5\text{D}_0$  state is also unsplit, if more than one component

**Figure 6** Spectra of the  $\text{Nd}^{3+}4\text{I}_{9/2} \rightarrow ^2\text{H}_{9/2}, ^4\text{F}_{5/2}$  transitions: (a) solid  $\text{Nd}(\text{BrO}_3)_3 \cdot 9\text{H}_2\text{O}$ ; (b)  $5.35 \times 10^{-2} \text{ M Nd}^{3+} (\text{aq})$ ; (c)  $5.35 \times 10^{-2} \text{ M Nd}^{3+}$  in  $11.4 \text{ M HCl}$ ; (d) solid  $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ ; (e)  $\text{Nd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ . is seen for this transition, it shows more than one europium site; only one line is observed for the crown ether complex shown in Figure 5 so the sites are identical. This transition is electric-dipole allowed and only observed in low-symmetry environments (it is not seen in the emission spectrum of the  $[\text{EuCl}_6]^{3-}$  ions in  $\text{Cs}_2\text{Li}[\text{EuCl}_6]$  where they occupy sites with cubic symmetry) whereas the intensity of the magnetic-dipole transition from  $^5\text{D}_0$  to  $^7\text{F}_1$  is relatively insensitive to this; in the spectrum of the crown ether complex this transition appears as a doublet and singlet, a splitting consistent with the approximately pentagonal pseudosymmetry seen in its crystal structure (in a lower-symmetry environment, the doublet would be further split).

Study of these and other transitions can thus yield valuable information. Crystals of the nine-coordinate complex  $[\text{Eu}(\text{tmhd})_3(\text{terpy})]$  contain two slightly different molecules present in the crystal, its luminescence spectrum showing a broad but unresolved  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  transition. In solid  $[\text{Eu}(\text{tmhd})_3(\text{Me}_2\text{phen})]$  ( $\text{Ln} = \text{La}, \text{Eu}, \text{Tb}, \text{Ho}$ ), there are two different square-antiprismatic isomers in the unit cell, and in this case emissions from both isomers can be distinguished in the fluorescence spectrum of the europium complex, which shows an unusually high splitting of the  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  transition.<sup>33</sup>

The paramagnetism of many lanthanide ions finds practical application in NMR shift reagents and, increasingly, in MRI contrast agents. EPR (*see Electron Paramagnetic Resonance*) spectra are only readily obtained from  $\text{Gd}^{3+}$ , with its  $^8\text{S}$  ground state,<sup>34</sup> as yet there has been little study of the effects of environment upon the spectra.

The electronic spectra and magnetic susceptibility of lanthanide complexes thus cannot be used to give diagnostic information on the stereochemistry of lanthanide compounds as for the 3d transition metals. Ultimately, reliable stereochemical information can only be obtained from diffraction measurements.

The lanthanides form a series of ions of closely related size and bonding characteristics and in many respects resemble  $\text{Ca}^{2+}$ , for which they often substitute isomorphously in biological systems; since different  $\text{Ln}^{3+}$  ions can be probed with particular spectroscopic techniques (e.g.  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  fluorescence,  $\text{Gd}^{3+}$  ESR,  $\text{Nd}^{3+}$  electronic spectra), in favorable circumstances it should be possible to obtain information about the binding site of spectroscopically inactive  $\text{Ca}^{2+}$  in several ways.<sup>35</sup>

### 3.6 Binary Compounds of Yttrium and the Lanthanides

#### 3.6.1 Halides<sup>36,37</sup>

These are the best characterized binary compounds of these metals; all the halides of the trivalent metals are well defined except  $\text{EuI}_3$ , whose existence is extremely uncertain. The insoluble fluorides are conveniently prepared by precipitation, followed by dehydration of the hydrate; this route is not generally open for the other anhydrous halides, as attempted dehydration of the hydrated halides tends to lead to oxyhalides. Reaction of the elements with the halogens or  $\text{HX}$  is often possible although a more convenient route involves heating the lanthanide oxide with the appropriate ammonium salt to afford  $(\text{NH}_4)_3\text{LnX}_6$ , followed by thermal decomposition. The halides may be purified by vacuum sublimation, with the caveat that the hot halides attack glass, forming the oxyhalide. The lanthanide trihalides very clearly demonstrate the effect of varying the cation and anion radii upon the structure type adopted (Table 2). As the radius of the lanthanide ion decreases on crossing the series from left to right, the coordination number of the metal in a given halide decreases; a similar effect is seen on descending group 17, as the radius of the halide ion increases.

The early fluorides feature the tysonite ( $\text{LaF}_3$ ; Figure 7) structure in which the lanthanide has nine nearest-neighbor fluorides in a tricapped trigonal prismatic array (like the aqua ions), with two rather more distant neighbors capping the trigonal faces. From  $\text{SmF}_3$  onwards the stable form is the

Figure 7 The  $\text{LaF}_3$  structure

'YF<sub>3</sub>' structure in which there is a distorted tricapped trigonal prismatic array of fluorines round the metal. The trichlorides adopt successively the UCl<sub>3</sub> (nine-coordinate), PuBr<sub>3</sub> (eight-coordinate), and AlCl<sub>3</sub> (six-coordinate) structures. A similar sequence is found in the bromides, while nine-coordinate is not found at all in the iodides; eight-coordinate is the rule for the early metals as far as promethium with six-coordinate for the later metals.

### 3.6.2 Lower Halides<sup>14,38</sup>

Whether an individual lanthanide forms a dihalide depends upon a number of factors, particularly the value of  $I_3$ , the third ionization energy.<sup>39</sup> There are three main types of lower halides.

1. The salt-like dihalides form the widest range. All MX<sub>2</sub> (X = F, Cl, Br, I) are formed by Eu, Sm, and Yb, the metals with the most stable divalent states; in addition, all except the difluoride are known for Nd, Dy, and Tm. They may typically be formed by reproporationation (comproportionation; see *Disproportionation*):

although hydrogen reduction is available for all the europium halides and all YbX<sub>2</sub> except YbF<sub>2</sub>. They are nonconductors and have magnetic and spectroscopic properties consistent with the presence of M<sup>2+</sup> ions. Only EuX<sub>2</sub> are stable for any length of time in aqueous solution. A range of solid-state structures is adopted; for example, all the difluorides have the fluorite structure.

2. Metallic diiodides are formed by La, Ce, Pr, and Gd, even though none of these lanthanides are well known in the divalent state. These have high conductivity, a metallic lustre, and are good reducing agents, reacting immediately with air and water. All the evidence supports the formulation Ln<sup>3+</sup>(I<sup>-</sup>)<sub>2</sub>(e<sup>-</sup>) with the free electron in a conduction band. A high-pressure form of NdI<sub>2</sub> is also believed to be of this type. The 'reduced' halide Pr<sub>2</sub>Br<sub>5</sub> is a Pr<sup>3+</sup> compound with the extra electron in a d-band. Extra Pr can be incorporated into PrCl<sub>3</sub> to give a black solid, Pr<sub>2.6</sub>Cl<sub>6</sub>, whose electronic structure is uncertain.
3. Cluster compounds are exemplified by Gd<sub>2</sub>Cl<sub>3</sub>, which has a structure (Figure 8) based on Gd<sub>6</sub>Cl<sub>8</sub> clusters sharing common edges in infinite chains. This, too, may be made by comproportionation; it is a semiconductor. Y<sub>2</sub>Cl<sub>3</sub>, Tb<sub>2</sub>Cl<sub>3</sub>, and Gd<sub>2</sub>Br<sub>3</sub> have also been described. Many compounds hitherto thought to be reduced binary halides are now known to be clusters containing a third, interstitial, element as in YClH. An extensive range of mixed metal halides based on chain structures exist. Thus, La<sub>4</sub>I<sub>5</sub>Ru has metal octahedra linked into chains with edge-bridging iodines; parallel chains are also linked by iodine

Figure 8 The Gd<sub>2</sub>Cl<sub>3</sub> structure

bridges, the whole structure having been described as a heterometal wire sheathed by iodine. Pr<sub>3</sub>I<sub>3</sub>Ru has a structure in which there are double chains of condensed, Ru-centered octahedra.

### 3.6.3 M<sup>IV</sup> Halides

The only tetrahalides isolated are the fluorides of Ce, Pr, and Tb. Only CeF<sub>4</sub> is made by direct fluorination of the metal (as well as CeX<sub>3</sub> (X = Cl, F)); the terbium compound is made by fluorination of TbF<sub>3</sub> while the more unstable PrF<sub>4</sub> is made by the reaction of Na<sub>2</sub>PrF<sub>6</sub> with dry HF (it decomposes around 70 °C). CeCl<sub>4</sub>, expected to be the most stable tetrachloride, has never been isolated (though Lewis base adducts have, cf. PuCl<sub>4</sub>).

### 3.6.4 Oxides<sup>40</sup>

The most important of these compounds are the basic sesquioxides M<sub>2</sub>O<sub>3</sub>, readily prepared by heating oxysalts such as the carbonate or nitrate:

though metals with an accessible (+4) state need a reducing atmosphere. They adopt three types of structures; in the A-type structure (La to Sm) they have capped-octahedral seven-coordinate, while in the B-type (Pr to Dy) face-capped trigonal prismatic seven-coordinate and a distorted capped-octahedral structure coexist. Distorted octahedral coordination is found in the C-type structure, the most stable phase for most lanthanides.

Reduction of Eu<sub>2</sub>O<sub>3</sub> with lanthanum or europium, as well as carbon, affords the stablest M<sup>II</sup> oxide:

Similar comproportionation has yielded NdO, SmO, and YbO, although in these cases it is necessary to work at high

pressure. Europium and samarium also give mixed-valence oxides  $M_3O_4$ .

Of the  $Ln^{IV}$  compounds,  $CeO_2$  is the most important. It is obtained as the product (white when pure, but usually yellow) of thermal decomposition of  $Ce^{III}$  oxy salts in air or by burning cerium metal. It has the fluorite structure. Additional phases,  $Ce_nO_{2n-2}$  ( $n = 7, 9, 10, 11$ ), have been characterized. A hydrated yellow form is precipitated from aqueous solution.  $CeO_2$  can be persuaded to dissolve in acid to afford  $Ce^{4+}$ , generally as a complex ion. Praseodymium and terbium usually form  $Pr_6O_{11}$  and  $Tb_4O_7$  when corresponding aerial ignition is employed, but can be produced as stoichiometric dioxides by heating with atomic oxygen. They dissolve in acid but no  $Ln^{IV}$  aqua ion can be made.

Several mixed metal oxides involving lanthanides have been found to exhibit *Superconductivity* (see *Superconductivity in Solids*) since the 1986 report of a superconducting transition temperature of 30 K in  $La_{2-x}Ba_xCuO_4$ , the highest found at that date. Shortly afterwards, a  $T_c$  of 93 K, above the boiling point of liquid nitrogen, was determined for  $YBa_2Cu_3O_7$ . Another class of superconductors, though with lower  $T_c$  values (20 K), are of the type  $Nd_{2-x}Ce_xCuO_4$ . These superconductors are believed to function by the so-called *Cooper Pair* mechanism in which electron pairs move unhindered by lattice vibrations and impurities. The conduction electrons probably reside primarily on the oxygen atoms. The cuprate superconductors have a common feature of two-dimensional copper oxide planes along which the superconductivity occurs; inserted between these layers are planes of metal atoms (or metal/oxygen atoms) which fulfil the function of acting as charge reservoirs.

The  $YBa_2Cu_3O_7$  compounds have been most extensively studied (Figure 9). Other, paramagnetic, lanthanide ions can be introduced in place of yttrium with little effect upon the conducting properties, arguing that the yttrium site has little involvement with the coppers but probably plays a supporting role. On the other hand, the presence of copper(II) is shown to be vital by other doping experiments. Above the superconducting region these compounds exhibit pronounced anisotropy in their resistance, it being greatest perpendicular to the  $CuO_2$  planes.

The commercial implications of 'warm' superconductors have led to intense study of the magnetic properties of these materials and the investigation of reliable synthetic routes, including the preparation of thin films.

### 3.6.5 Other Binary Compounds

Hydrides are readily formed by union of these metals with hydrogen on gentle warming.<sup>41</sup> Apart from europium, which only forms  $EuH_2$ , both  $LnH_2$  and  $LnH_3$  exist, although the composition ranges can be considerable and the phase isolated is often nonstoichiometric (thus for yttrium the stability ranges are  $YH_{1.90-2.23}$  and  $YH_{2.77-3.0}$ ). Both types of hydride contain  $Ln^{3+}$  ions with the trihydrides as salt-like  $Ln^{3+}(H^-)_3$  while

**Figure 9** The structure of  $YBa_2Cu_3O_7$ ; the shaded atoms are those removed to create oxygen-deficient phases up to  $YBa_2Cu_3O_6$ . (Ref. 6. Reproduced by permission of Palgrave Macmillan)

the conducting dihydrides are  $Ln^{3+}(H^-)_2(e^-)$ . The important alloy hydride  $LaNi_5H_6$  is discussed in Section 3.3.

The lanthanides form a range of borides.<sup>42</sup> The most important of these is high-melting ( $2715^\circ C$ )  $LaB_6$ , widely used as a high-intensity thermal cathode in electron guns and in optical fibres. It has the  $CaB_6$  structure and may be made by various routes, including  $La_2O_3$  and B at  $1500^\circ C$ .  $LaB_4$  (UB<sub>4</sub> type) and  $LaB_9$  are also known.  $EuB_6$  has been used as a neutron absorber in nuclear reactors; like  $YbB_6$  it has  $Ln^{2+}$  ions, in contrast to the other hexaborides which contain  $Ln^{3+}$  ions, affording one electron from each lanthanide to provide a conduction band, and are metallic conductors. Many heavier lanthanides (above Gd) form  $MB_{12}$  (UB<sub>12</sub> structure) and  $MB_{66}$  in which a  $B_{12}$  icosahedron is surrounded by 12 linked  $B_{12}$  icosahedra. A number of important ternary borides exist, particularly  $Nd_2Fe_{14}B$ , a high coercive-strength ferromagnet, while related compounds with other lanthanides are important in magnet technology. In addition to these, a number of  $LnRh_4B_4$  compounds with the  $CeCo_4B_4$  structure have been investigated for their superconducting properties.

An extensive array of sulfides has been obtained, and much research is still undertaken to clarify the picture.<sup>43-45</sup> The most important are sesquisulfides,  $M_2S_3$ , but other stoichiometries ( $MS$ ,  $M_3S_4$ , and  $MS_2$ ) also exist. A range of synthetic methods has been employed for the sesquisulfides (apart from the nonexistent  $Eu_2S_3$ ); reaction of the lanthanide powders with sulfur in the presence of alkali-metal chlorides as a flux has found favor lately, as has reaction of the

sesquioxide or reduced chloride or chloride hydrides with sulfur. These compounds do contain the  $\text{Ln}^{3+}$  ions and often exist in several crystalline forms, sometimes obtained from high-pressure/temperature synthesis. The  $\alpha$ -form (La–Dy) has seven- and eight-coordinate metals, the high-temperature  $\gamma$ -form (La–Dy) involves eight-coordination; the  $\delta$ -form (Y, Ho–Tm) has six- and seven-coordination, while the  $\varepsilon$ -form (Yb, Lu) has six-coordination only.  $\text{M}_3\text{S}_4$  ( $\text{Th}_3\text{P}_4$  structure) are generally found for the early lanthanides (La–Sm); most have  $\text{Ln}^{3+}$  but  $\text{Eu}_3\text{S}_4$  contains both di- and trivalent europium. The monosulfides  $\text{LnS}$  are mainly golden yellow solids (NaCl structure) with a metallic luster whose metallic conductivity indicates a structure  $\text{Ln}^{3+}(\text{S}^{2-})(\text{e}^-)$ , but the europium, ytterbium, and samarium compounds are insulators,  $\text{Ln}^{2+}\text{S}^{2-}$ .

Carbides are likewise formed in a number of stoichiometries.<sup>46</sup>  $\text{LnC}_2$  are the most important; they can be made by direct synthesis from the elements as well as by heating the oxide or hydride with carbon. They have the  $\text{CaC}_2$  structure with short C–C distances (around 1.28 Å) but have metallic conductivity and thus may be formulated  $\text{Ln}^{3+}(\text{C}_2^{2-})(\text{e}^-)$ .  $\text{C}_2$  units are also found in  $\text{Ln}_2\text{C}_3$  ( $\text{Pu}_2\text{C}_3$  structure), while  $\text{LnC}$ ,  $\text{Ln}_2\text{C}$ , and  $\text{Ln}_3\text{C}$  are also known. The carbides are readily hydrolyzed, affording a mixture of hydrocarbons whose composition depends on temperature.

Another kind of lanthanide–carbon binary compound recently discovered are the fullerenes (see **Carbon: Fullerenes**); vaporization of graphite–Ln or graphite– $\text{Ln}_2\text{O}_3$  mixtures followed by toluene extraction of the resulting soot affords a number of clusters identifiable by mass spectroscopy, particularly  $\text{Ln}@\text{C}_{82}$ . ESR studies on the air-stable  $\text{La}@\text{C}_{82}$  and  $\text{Y}@\text{C}_{82}$  indicate the formulation  $\text{Ln}^{3+}@\text{(C}_{82}\text{)}^{3-}$ ; thus the spectrum of the lanthanum compound consists of eight lines of equal intensity due to hyperfine coupling to a single La ( $I = 7/2$ ). An *Extended X-ray Absorption Fine Structure* (EXAFS) study on  $\text{Y}@\text{C}_{82}$  indicated that yttrium has seven carbon neighbors (2.35 Å) and one yttrium (at 4.05 Å), suggesting a dimeric formulation.

Practically all  $\text{LnQ}$  ( $\text{Q} = \text{Group 15 element}$ ) having the NaCl structure are made by direct synthesis, with other routes for the nitrides including the reaction of the lanthanide hydride with either nitrogen or ammonia; like the carbides, they are readily hydrolyzed to the hydride  $\text{QH}_3$ .

### 3.6.6 The Hydroxides

These metals form genuine hydroxides (not hydrous oxides) by alkaline precipitation from aqueous solution, obtainable in crystalline form by hydrothermal methods (crystallization from hot  $\text{Ln}_2\text{O}_3/\text{NaOH}$  under pressure). All have the nine-coordinate  $\text{UCl}_3$  structure, except for  $\text{Lu}(\text{OH})_3$  which adopts the six-coordinate  $\text{In}(\text{OH})_3$  structure. Like the oxides, their basicity extends to reaction with atmospheric  $\text{CO}_2$ , affording the carbonates.

<sup>a</sup>Data for solution of a slightly different ionic strength.

## 3.7 Coordination Chemistry of the +3 State<sup>5,6,47,48</sup>

Selected stability constants for scandium, yttrium, lanthanum, and lutetium are shown in (Table 3)<sup>49</sup> They show a preference for ‘hard’ donor atoms, as might be expected for the trivalent metals, but complexes with softer donor atoms like nitrogen can be isolated by operating in nonaqueous solvents.

### 3.7.1 Coordination Numbers and Geometries in Lanthanide Complexes<sup>50</sup>

As already noted, because of the large size of the lanthanide ion, it often occurs in high-coordination compounds (see **Coordination Numbers & Geometries**). Application of a cone-packing model (see *Cone Angle*) to lanthanide complexes indicates that the coordination number adopted is a consequence of saturation in the coordination sphere. Analysis of the coordination numbers (see **Coordination Numbers & Geometries**) for large numbers of coordination compounds of yttrium and the lanthanides indicates that coordination numbers of eight and nine are almost equally common, accounting for over 60% of the known structures. These are, of course, the coordination numbers associated with the aqua ions and related complexes.

Two coordination is known in the form of the monomeric (bent) alkyls  $[\text{Ln}\{\text{C}(\text{SiMe}_3)_3\}_2]$  ( $\text{Ln} = \text{Eu}, \text{Yb}$ ) which feature additional agostic interactions.<sup>51</sup> Coordination numbers of 3–5 are similarly associated with the use of bulky ligands, such as alkoxide (and related systems), bis(trimethylsilyl)amido, and the isolobal alkyl  $\text{CH}(\text{SiMe}_3)_2$  (see **Scandium, Yttrium & the Lanthanides: Organometallic Chemistry**). Several homoleptic three-coordinate  $\text{LnX}_3$  systems are formed by these ligands, a few having the expected trigonal planar geometry, but usually they are pyramidal. The adoption of this geometry has, in the case of actinide trialkyls, been attributed to 6d involvement in the bonding; here it appears that weak agostic interactions are important in the solid state (the alkylamides have zero dipole moment in

solution and thus appear to be planar there, though pyramidal in the solid state). Tetrahedral geometry is, as expected, found in the four-coordinate  $[\text{Lu}(\text{2,6-dimethylphenyl})_4]^-$  ion and in  $\text{Ln}[(\text{N}(\text{SiMe}_3)_2)_3(\text{Ph}_3\text{PO})]$ ; in the latter complex the ligands have high second-order steric effects (*see Fan Angle*), generating crowding round the lanthanide even though there are only four atoms bound to the lanthanide. In contrast, the adoption of six-coordination in the  $\text{LnCl}_6^{3-}$  anion is the result of first-order crowding among the six chlorides bound to the lanthanide. The six-coordinate complexes are usually octahedral, though with bidentate S-donors distortion towards trigonal prismatic may be the result of steric interactions between ligands. The first lanthanide thiocyanate complex to be characterised was the six-coordinate  $[\text{Er}(\text{NCS})_6]^{3-}$  ion, as the tetrabutylammonium salt; since then, crystallographic study of many lanthanide thiocyanate complexes has shown that seven and eight-coordination are also possible with the coordination number adopted being the result of a subtle balance of factors including the counterion and solvent used (Section 3.7.10).

Among seven-coordinate structures, many involve dicationate complexes  $\text{Ln}(\text{diket})_3 \cdot \text{L}$ ; these generally have either capped-octahedral or capped trigonal prismatic geometry. A considerable number of complexes with neutral donors (e.g. thf) of the type  $\text{LnX}_3\text{L}_4$  ( $\text{X}$  = halide, NCS), however, have structures closest to pentagonal bipyramidal, similarly found in the erbium perchlorate complex with 2,6-dimethyl-4-pyrone (Section 3.7.4).

Most eight-coordinate lanthanide complexes have dodecahedral or square-antiprismatic geometries; the energy difference between these is likely to be small. One exception is the  $[\text{La}(\text{bipyO}_2)_4]^{3+}$  ion, which is cubic, possibly because of solid-state packing effects. Tricapped trigonal prismatic is the most familiar example of nine-coordinate geometry, adopted for the nonaqua ions of all lanthanides in a number of crystalline salts. This geometry is also often adopted where polydentate ligands are involved, such as the tris complexes with terpy and dipicolinate, even in  $\text{Eu}(\text{dpm})_3 \cdot \text{terpy}$ .

Steric considerations (interdonor atom repulsions) make coordination numbers of 10 or more difficult, so fewer examples are known and, moreover, small differences between different types of polyhedra make assignment of a particular geometry difficult. Most examples involve nitrate, either alone (Section 3.7.7), or in combination with other polydentate ligands such as crown ethers (Section 3.7.8). Near-icosahedral geometries are found for regular 12-coordinate complexes such as  $\text{Pr}(\text{naph})_6^{3+}$  and  $\text{Ln}(\text{NO}_3)_6^{3-}$ .

Lanthanide complexes display a richness of coordination number and geometry unmatched by any other block of metals. It is becoming increasingly clear that in the absence of the strong ligand-field forces that often dictate coordination geometries in transition metal complexes, the coordination number adopted and the species formed in the solid state depends on the balance of a number of factors.

### 3.7.2 Aqua Ions and Simple Hydrated Salts<sup>5,52</sup>

Hydrated salts are readily prepared by reaction of the lanthanide oxide or carbonate with the acid. Salts of non coordinating anions most often crystallise as salts  $[\text{Ln}(\text{OH}_2)_9]\text{X}_3$  ( $\text{X}$  e.g. bromate, triflate, ethylsulphate, tosylate). The tricapped trigonal prismatic structure was first established by X-ray diffraction in 1939 for the  $[\text{Nd}(\text{H}_2\text{O})_9]^{3+}$  ion in  $[\text{Nd}(\text{H}_2\text{O})_9](\text{BrO}_3)_3$ ; this was an important structure historically, as it was the first clear indication that lanthanides could have high coordination numbers. It has since been verified for many other salts (Figure 10).

The crystals of the triflate contain columns of  $[\text{Ln}(\text{OH}_2)_9]^{3+}$  cations and  $\text{CF}_3\text{SO}_3^-$  ions, with a three-dimensional network of hydrogen bonds linking the columns. This presumably helps stabilise this structure favoring its isolation, even for the later lanthanides (Gd–Lu), where the eight-coordinate  $[\text{Ln}(\text{OH}_2)_8]^{3+}$  ion predominates in solution (the  $[\text{Ln}(\text{OH}_2)_8]^{3+}$  cation can be crystallised with certain other counter ions, for example,  $[\text{terpyH}_2]_2[\text{Tb}(\text{OH}_2)_8]\text{Cl}_7 \cdot 8/3\text{H}_2\text{O}$ ,  $[\text{Er}(\text{OH}_2)_8](\text{ClO}_4)_3 \cdot (\text{dioxan}) \cdot 2\text{H}_2\text{O}$ ;  $[\text{Eu}(\text{OH}_2)_8]_2(\text{V}_{10}\text{O}_{28}) \cdot 8\text{H}_2\text{O}$  and  $[\text{Lu}(\text{OH}_2)_8]^{3+}$  in  $[\text{Lu}(\text{OH}_2)_8]\text{Cl}_3 \cdot 1.5(12\text{-crown-4}) \cdot 2\text{H}_2\text{O}$ , as well as in several hydrated iodides), and similar arguments are likely to apply to the ethylsulphates and bromates. The lanthanide–water distances for the positions capping the prism faces and at the vertices are different; as the lanthanide series is crossed, the Ln–O distance decreases from 2.62 to 2.50 Å for the three face-capping oxygens, but more steeply from ca. 2.52 to 2.29 Å for the six apical oxygens (data for the triflate salt<sup>53</sup>); the corresponding distances in the ethyl sulfates show a similar trend, with the Ln–O distances decreasing from 2.616 to 2.497 Å (face-capping) and from 2.517 to 2.318 Å (apical) on passing from La to Lu.

Octahedral six-coordination is, however, rather surprisingly found in the rather unstable perchlorates  $[\text{Ln}(\text{H}_2\text{O})_6]^{3+}(\text{ClO}_4^-)_3$  ( $\text{X}$ -ray,  $\text{Ln} = \text{La}, \text{Tb}, \text{Er}$ ), although the dioxane complexes  $\text{Ln}(\text{ClO}_4)_3 \cdot 9\text{H}_2\text{O} \cdot 4$  dioxane may contain the nonaqua ions. The isolation of  $\text{Ln}(\text{ClO}_4)_3 \cdot 6\text{H}_2\text{O}$  in the solid state must

Figure 10 The structure of the nonaqua lanthanide ion

reflect a balance of factors such as solubility and hydrogen-bonding in the solid state, as the close similarity between the EXAFS spectra of aqueous solutions of lanthanum perchlorate and the spectrum of solid  $[\text{Ln}(\text{H}_2\text{O})_9](\text{CF}_3\text{SO}_3)_3$ , indicates a coordination number of 9 for  $\text{La}^{3+}$  (aq) in the perchlorate solutions. Similarly, the fact that erbium is eight-coordinate in  $[\text{Er}(\text{OH}_2)_8](\text{ClO}_4)_3 \cdot (\text{dioxan}) \cdot 2\text{H}_2\text{O}$  shows the fine balance here. Lower hydrates than the hexahydrates exist. Partial dehydration of  $\text{Ln}(\text{ClO}_4)_3 \cdot 6\text{H}_2\text{O}$  ( $\text{Ln} = \text{Er}, \text{Lu}$ ) gives  $\text{Lu}(\text{ClO}_4)_3 \cdot 3\text{H}_2\text{O}$  and  $\text{Er}(\text{ClO}_4)_3 \cdot \text{H}_2\text{O}$ , both of which have eightfold coordination of the lanthanide. Similarly,  $\text{Yb}(\text{ClO}_4)_3 \cdot \text{H}_2\text{O}$  has been shown to have bi and tridentate perchlorate groups giving eight-coordinate ytterbium.

When anions can coordinate, a wide variety of species is obtained. Thus, whilst early lanthanides ( $\text{La-Nd}$ ) form  $[\text{Ln}(\text{OH}_2)_9](p\text{-MeC}_6\text{H}_4\text{SO}_3)_3$  with the usual trigonal prismatic coordination, the later lanthanide ions form the tosylates  $\text{Ln}(p\text{-MeC}_6\text{H}_4\text{SO}_3)_3 \cdot 9\text{H}_2\text{O}$ , which contain  $[\text{Ln}(\text{OH}_2)_6(p\text{-MeC}_6\text{H}_4\text{SO}_3)_2]^+$  ions ( $\text{Ln} = \text{Sm}, \text{Gd}, \text{Dy}, \text{Ho}, \text{Er}, \text{Yb}, \text{Y}$ ) in distorted dodecahedral eight-coordination.

A considerable number of nitrates  $\text{Ln}(\text{NO}_3)_3 \cdot n\text{H}_2\text{O}$  have been examined; in general, the coordination number of the lanthanide decreases with decreasing ionic radius and all nitrate groups are coordinated as bidentate ligands in these compounds, but the number of waters of crystallisation is no guide to how many are actually bound to the metal. Thus  $\text{Ln}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  are known for  $\text{La-Dy}$  and  $\text{Y}$ . Of these, the lanthanum and cerium compounds are  $[\text{Ln}(\text{NO}_3)_3 \cdot (\text{H}_2\text{O})_5] \cdot \text{H}_2\text{O}$  ( $\text{Ln} = \text{La}, \text{Ce}$ ) with 11-coordinate lanthanides, whilst the others are  $[\text{Ln}(\text{NO}_3)_3 \cdot (\text{H}_2\text{O})_4] \cdot 2\text{H}_2\text{O}$  ( $\text{Ln} = \text{Pr-Dy}, \text{Y}$ ) with 10-coordination for the metal.  $[\text{Ln}(\text{NO}_3)_3 \cdot (\text{H}_2\text{O})_4]$  molecules are also present in the pentahydrates  $\text{Ln}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$  ( $\text{Ln} = \text{Eu}, \text{Dy-Yb}$ ). Lutetium forms  $\text{Lu}(\text{NO}_3)_3 \cdot 4\text{H}_2\text{O}$  and  $\text{Lu}(\text{NO}_3)_3 \cdot 3\text{H}_2\text{O}$ , isolated under very similar conditions, both of which contain nine-coordinate  $[\text{Lu}(\text{NO}_3)_3 \cdot (\text{H}_2\text{O})_3]$  molecules. Nine-coordinate  $\text{Yb}(\text{NO}_3)_3(\text{H}_2\text{O})_3$  has also been identified. Additionally,  $\text{Ln}(\text{NO}_3)_3(\text{H}_2\text{O})_3$  molecules ( $\text{Ln} = \text{Gd}, \text{Ho}, \text{Y}, \text{Lu}$ ) have been found in adducts with noncoordinating crown ether and bipy ligands.<sup>54</sup>

Among the halides, the chlorides of  $\text{La}$  and  $\text{Ce}$ ,  $\text{LnCl}_3 \cdot 7\text{H}_2\text{O}$  are dimeric  $[(\text{H}_2\text{O})_7\text{Ln}(\mu\text{-Cl})_2\text{Ln}(\text{OH}_2)_7]\text{Cl}_4$  with what has been described as singly capped square-antiprismatic coordination of the metals (Figure 11) whilst  $\text{LnCl}_3 \cdot 6\text{H}_2\text{O}$  ( $\text{Ln} = \text{Ce-Lu}$ ) have antiprismatic  $[\text{LnCl}_2(\text{H}_2\text{O})_6]^+$  ions with the coordinated chlorides on opposite sides of the polyhedron. There are extensive hydrogen-bonding networks involving both coordinated and noncoordinated chlorides and water molecules.<sup>55</sup>

The hydrated bromides tend to resemble the chlorides;  $\text{La}$  and  $\text{Ce}$  form  $\text{LnBr}_3 \cdot 7\text{H}_2\text{O}$ , isomorphous with the corresponding chlorides and are dimeric  $[(\text{H}_2\text{O})_7\text{Ln}(\mu\text{-Br})_2\text{Ln}(\text{OH}_2)_7]\text{Br}_4$ .  $\text{LnBr}_3 \cdot 6\text{H}_2\text{O}$  ( $\text{Ln} = \text{Pr-Dy}$ ) are  $[\text{LnBr}_2(\text{H}_2\text{O})_6]\text{Br}$  whilst  $\text{LnBr}_3 \cdot 8\text{H}_2\text{O}$  ( $\text{Ln} = \text{Ho-Lu}$ ) which are  $[\text{Ln}(\text{H}_2\text{O})_8]\text{Br}_3$ , with no bromide coordinated, and which resemble the hydrated

**Figure 11** Structure of the dimeric cation  $[(\text{H}_2\text{O})_7\text{LnCl}_2\text{Ln}(\text{H}_2\text{O})_7]^{4+}$

iodides of the heavier lanthanides. Study of the hydrated iodides has been difficult because of their deliquescence and their tendency to oxidation in air. Iodide does not coordinate to the metal in any of them. The iodides of the earlier lanthanides are  $\text{LnX}_3 \cdot 9\text{H}_2\text{O}$  ( $\text{Ln} = \text{La-Ho}$ ),<sup>56</sup> containing the familiar tri-capped trigonal prismatic  $[\text{Ln}(\text{OH}_2)_9]^{3+}$  ions, but the range of  $\text{Ln-O}$  distances is much smaller than in the triflates and ethylsulphates, falling in the range 2.552–2.576 Å for  $\text{Ln} = \text{La}$  and similarly between 2.403 and 2.405 Å for the  $\text{Ho}$  complex. Heavier lanthanides ( $\text{Ln} = \text{Er-Lu}$ ) form  $\text{LnI}_3 \cdot 10\text{H}_2\text{O}$ , containing square-antiprismatic  $[\text{Ln}(\text{OH}_2)_8]^{3+}$  ions. The little-known thiocyanates form hexa- and heptahydrates; heptahydrates contain  $\text{Ln}(\text{NCS})_3(\text{H}_2\text{O})_6$  molecules ( $\text{Ln} = \text{La-Dy}$ ) and hexahydrates have  $\text{Ln}(\text{NCS})_3(\text{H}_2\text{O})_5$  ( $\text{Ln} = \text{Sm-Eu}$ ) molecules, in each case the crystal containing one uncoordinated water molecule.

A number of hydrated sulfates exist. The nonahydrates of  $\text{La}$  and  $\text{Ce}$  have two distinct lanthanide sites, one nine-coordinate (six waters and three monodentate sulfates) the other featuring 12-coordination (six waters and three bidentate sulfates). The other lanthanides form octahydrates with eight-coordination; the larger lanthanides also form pentahydrates such as  $\text{Nd}_2(\text{SO}_4)_3 \cdot 5\text{H}_2\text{O}$  in which the metal is nine-coordinate (distorted trigonal prism) by seven sulfate oxygens and two water molecules.

The chloride, bromide, bromate, perchlorate, nitrate, acetate, and iodide salts are all soluble (the latter two types rather less than the others); the sulfates are sparingly soluble but the fluorides, carbonates, oxalates, and phosphates are insoluble.

### 3.7.3 Aqua Ions

The number of water molecules in the coordination sphere of the hydrated  $\text{Ln}^{3+}$  ion has been intensively studied for many years.<sup>5</sup> It now appears most probable that there is a change in coordination number from nine to eight for

$\text{Ln}(\text{H}_2\text{O})_n^{3+}$  in mid-series, with the shape of the complex ion changing from tricapped trigonal prismatic nine-coordination for the lighter, larger, lanthanides to square-antiprismatic eight-coordination for the later metals, the changeover region (Sm to Tb) appearing to involve a mixture of eight- and nine-coordinate species. This view is based on information from a range of sources. A neutron-diffraction study of  $\text{Nd}(\text{ClO}_4)_3$  and  $\text{Sm}(\text{ClO}_4)_3$  in solution indicated coordination numbers of 9.0 and 8.5 respectively, with values of 7.9 for Dy and Lu, indicating that there are both eight- and nine-coordinate species present for samarium. EXAFS spectra (*see Extended X-ray Absorption Fine Structure*) of aqueous solutions of lanthanum perchlorate<sup>57</sup> are in close agreement with solid  $[\text{Ln}(\text{H}_2\text{O})_9](\text{CF}_3\text{SO}_3)_3$ , suggesting a coordination number of 9 for  $\text{La}^{3+}$  (aq). In a study of chloride complexation by the lanthanides, EXAFS was used to determine hydration numbers of the aqua ions as 9.2 (La); 9.3 (Ce); 9.5 (Nd); 9.3 (Eu); 8.7 (Yb) and 9.7 (Y). Information from hydration studies of lanthanide ions by laser-induced fluorescence spectroscopy has been combined with other techniques to indicate a change in hydration number from 9 to 8 in the Eu–Tb region of the series. A luminescence study of lanthanide complexes reveals a linear correlation between the decay constant and the number of coordinated water molecules, used to calculate first coordination sphere hydration numbers of 9.0, 9.1, 8.3 and 8.4 for  $\text{Sm}^{3+}$ ,  $\text{Eu}^{3+}$ ,  $\text{Tb}^{3+}$ , and  $\text{Dy}^{3+}$ , respectively.

### 3.7.4 Complexes of Other O-Donor Ligands<sup>4,5</sup>

Complexes of ligands such as phosphine and arsine oxides were the first complexes of this type to be isolated from nonaqueous solvents. Among the studies of lanthanide halide complexes with these ligands,  $[\text{Ln}(\text{Ph}_3\text{PO})_5\text{Cl}](\text{FeCl}_4)_2$  ( $\text{Ln} = \text{La–Nd, Sm–Er, Y}$ ) and  $[\text{Gd}(\text{Ph}_3\text{PO})_4\text{Cl}_2]\text{CuCl}_3$  show that it is possible to pack several of these bulky ligands around a lanthanide.  $\text{YF}_3 \cdot 0.5\text{H}_2\text{O}$  shows no signs of reaction with these ligands, but many complexes exist with other halides, most structurally confirmed examples involving yttrium, as in *trans*- $[\text{YCl}_2(\text{Ph}_3\text{PO})_4]\text{Cl} \cdot 2.5\text{EtOH} \cdot \text{H}_2\text{O}$ , *trans*- $[\text{YBr}_2(\text{Ph}_3\text{PO})_4]\text{PF}_6 \cdot \text{Et}_2\text{O}$  and  $[\text{Y}(\text{Me}_3\text{PO})_6]\text{Br}_3$ , all with octahedrally coordinated yttrium. Other stoichiometries isolated include  $[\text{YX}_3(\text{Ph}_2\text{MePO})_3]$  ( $\text{X} = \text{Cl, Br, I}$ ) and  $[\text{YCl}(\text{Ph}_3\text{PO})_5](\text{SbCl}_6)_2 \cdot \text{CeCl}_3 \cdot 6\text{H}_2\text{O}$  reacts with  $\text{Me}_3\text{PO}$  in MeOH forming  $[\text{Ce}(\text{Me}_3\text{PO})_4\text{Cl}_3] \cdot 4\text{H}_2\text{O}$ ; on slow crystallisation of a  $\text{MeNO}_2$  solution in air, crystals of  $[\text{Ce}(\text{Me}_3\text{PO})_4(\text{H}_2\text{O})_4]\text{Cl}_3 \cdot 3\text{H}_2\text{O}$  result, cerium having triangulated dodecahedral coordination.

A considerable number of nitrate complexes have been examined.<sup>58</sup> The precise experimental conditions can be very important in their synthesis; thus the reaction of  $\text{Y}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  with 1 or 2 mols of  $\text{Ph}_3\text{PO}$  in boiling EtOH gives  $[\text{Y}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_2(\text{EtOH})]$  whilst 4 of triphenylphosphine oxide gives  $\text{Y}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_3$ , and reaction with 6 mols of  $\text{Ph}_3\text{PO}$  in cold ethanol affords  $\text{Y}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_4$ , the latter being  $[\text{Y}(\text{NO}_3)_2(\text{Ph}_3\text{PO})_4]\text{NO}_3$ . Lanthanide nitrates react

with excess  $\text{Ph}_3\text{PO}$  in acetone forming  $[\text{Ln}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_4]$  ( $\text{Ln} = \text{La–Nd}$ ) which are  $[\text{Ln}(\eta^2\text{-NO}_3)_2(\eta^1\text{-NO}_3)(\text{Ph}_3\text{PO})_4]$ , but in solution ( $\text{Me}_2\text{CO}$  or  $\text{CH}_2\text{Cl}_2$ ) they dissociate into  $[\text{Ln}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_3]$  (the only product of reaction in ethanol) and  $\text{Ph}_3\text{PO}$ .  $[\text{La}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_3] \cdot \text{CHCl}_3 \cdot \text{EtOH}$  has three bidentate nitrate groups.  $[\text{Ln}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_3]$  are the only products for the nitrates of Sm–Gd. The later lanthanide nitrates (Tb–Lu) give crystals of  $[\text{Ln}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_3] \cdot 2\text{Me}_2\text{CO}$  in propanone, but  $[\text{Ln}(\text{NO}_3)_2(\text{Ph}_3\text{PO})_4]\text{NO}_3$  in cold ethanol.

A number of  $[\text{Ln}(\text{NO}_3)_3(\text{Ph}_3\text{PO})_2(\text{EtOH})]$  ( $\text{Ln} = \text{Ce, Nd, Sm, Eu}$ ) have also been confirmed. With the less bulky  $\text{Ph}_2\text{MePO}$ ,  $[\text{Ln}(\eta^2\text{-NO}_3)_3(\text{Ph}_2\text{MePO})_3]$  are isolated for all lanthanides, and  $[\text{La}(\eta^2\text{-NO}_3)_3(\text{Ph}_2\text{MePO})_4]$ , for La only.  $\text{Ph}_3\text{AsO}$  forms  $[\text{La}(\text{NO}_3)_2(\text{Ph}_3\text{AsO})_4]\text{NO}_3$ ,  $[\text{La}(\text{NO}_3)_3(\text{Ph}_3\text{AsO})_3]$ , and  $[\text{La}(\text{NO}_3)_3(\text{Ph}_3\text{AsO})_2(\text{EtOH})]$ . A range of complexes have been made for the even less demanding  $\text{Me}_3\text{AsO}$ , such as  $[\text{La}(\text{Me}_3\text{AsO})_6](\text{NO}_3)_3$ ,  $[\text{La}(\eta^2\text{-NO}_3)_2(\eta^1\text{-NO}_3)(\text{Me}_3\text{AsO})_4]$  and  $[\text{Eu}(\text{NO}_3)_3(\text{Ph}_3\text{AsO})_3]$ .

Lanthanide triflates reacts with  $\text{Ph}_3\text{PO}$  in ethanol forming  $[\text{Ln}(\text{OTf})_2(\text{Ph}_3\text{PO})_4]\text{OTf}$  ( $\text{Ln} = \text{La, Nd, Er, Lu}$ ). The erbium and lutetium compounds have octahedral coordination, with monodentate triflates, but the complexes of the larger La and Nd have seven-coordination with one triflate being bidentate.

Using hexamethylphosphoramide ( $(\text{Me}_2\text{N})_3\text{PO}$ ) as a ligand, two series are obtained in which the stoichiometry is maintained across the series,  $\text{Ln}(\text{HMPA})_6(\text{ClO}_4)_3$  and  $\text{Ln}(\text{HMPA})_3\text{Cl}_3$ ; these are verified crystallographically for  $[\text{Nd}(\text{HMPA})_6](\text{ClO}_4)_3$  and *mer*- $[\text{Ln}(\text{HMPA})_3\text{Cl}_3]$  ( $\text{Ln} = \text{Pr, Yb}$ ). Apart from the direct reaction between the ligand and the appropriate metal salt, such complexes have been made by an unusual ‘one-pot’ synthesis<sup>59</sup> by heating the ligand, metal (e.g. La), and the appropriate ammonium salt together in toluene, leading to the isolation of nine-coordinate  $\text{La}(\text{HMPA})_3(\text{NO}_3)_3$ , seven-coordinate  $\text{La}(\text{HMPA})_4(\text{NCS})_3$  (Figure 12), and  $\text{La}(\text{HMPA})_4\text{Br}_3$ . Isomorphous *fac*- $[\text{LnCl}_3(\text{HMPA})_3]$  ( $\text{Ln} = \text{La, Pr, Nd, Sm, Eu, Gd}$ ) have also been synthesised to set alongside the *mer*-isomers; the isomerisation can be followed in solution by NMR, and is believed to occur by an associative mechanism.<sup>60</sup>

The application of a solution of  $\text{SmI}_2$  in hexamethylphosphoramide as a one-electron reductant in organic syntheses has led to numerous studies of samarium complexes of HMPA.  $[\text{SmI}_3(\text{HMPA})_4]$ , prepared from Sm and  $\text{CH}_2\text{I}_2$  in HMPA/thf, scavenges traces of water forming  $[\text{Sm}(\text{HMPA})_2(\text{H}_2\text{O})_5]\text{I}_3 \cdot 2\text{HMPA}$  and  $[\text{Sm}(\text{H}_2\text{O})_4(\text{HMPA})_3]\text{I}_3$ , both with pentagonal bipyramidally coordinated samarium. Other such complexes reported are  $[\text{Sm}(\text{H}_2\text{O})_5(\text{HMPA})_2]\text{I}_3(\text{HMPA})_2$ ,  $[\text{Sm}(\text{H}_2\text{O})_3(\text{HMPA})_4]\text{I}_3$ ,  $[\text{SmBr}_3(\text{HMPA})_2(\text{thf})]$ ,  $[\text{SmBr}_2(\text{HMPA})_4]\text{Br} \cdot \text{thf}$ ,  $[\text{SmCl}(\text{H}_2\text{O})_4(\text{HMPA})_2]\text{Cl}_2 \cdot \text{thf}$ ,  $[\text{SmCl}(\text{HMPA})_5](\text{BPh}_4)_2$ ,  $[\text{Sm}(\text{O}_3\text{SCF}_3)_2(\text{HMPA})_4](\text{O}_3\text{SCF}_3)$ ,  $[\text{Sm}(\text{O}_3\text{SCF}_3)_3(\text{H}_2\text{O})(\text{HMPA})_3]$  and  $[\text{Sm}(\text{HMPA})_3(\eta^2\text{-NO}_3)_3]$ .<sup>61</sup>

Seven-coordination (distorted pentagonal bipyramidal) is found in the complex of 2,6-dimethylpyrone, Er

Figure 12 Structure of seven-coordinate  $\text{La}(\text{HMPA})_4(\text{NCS})_3$

$(\text{DMP})_7(\text{ClO}_4)_3$ ; with the earlier lanthanides this ligand forms  $\text{Ln}(\text{DMP})_8(\text{ClO}_4)_3$ , presumably eight-coordinate.

Tetrahydrofuran complexes of the lanthanide chlorides are useful synthetic starting materials where a readily soluble form of the halide is needed, for example, in the synthesis of compounds such as alkoxides, aryloxides, alkylamides, and organometallics in general, though their stoichiometry can be uncertain owing to ready loss of the Lewis base. They are difficult to prepare from the hydrated chlorides; perhaps the best route is sonication of lanthanide powders and  $\text{C}_2\text{Cl}_6$  in thf. There is a wide range of stoichiometry and structure,<sup>59</sup> with complexes  $\text{LnCl}_3(\text{thf})_x$  ( $x = 2, 2.5, 3, 3.5, 4$ ) identified, and six different structure types confirmed. The compound actually isolated depends upon the reaction conditions, stoichiometry and the lanthanide concerned. Across the series, there is a decrease in coordination number from 8 (La) to 6 (Lu). Lanthanum is unique in forming  $[\text{LaCl}_3(\text{thf})_2]$  which is a single-stranded polymer  $\dots\text{La}(\mu\text{-Cl})_3(\text{thf})_2\text{La}(\mu\text{-Cl})_3(\text{thf})_2\text{La}\dots$  with *cis*-thf molecules and square-antiprismatic eight-coordinate of lanthanum. Compounds of the same stoichiometry,  $[\text{LnCl}_3(\text{thf})_2]$  are isolated for Ce–Nd, but have different structures, though again polymeric, in this case with seven-coordinate  $\dots\text{LnCl}(\text{thf})_2(\mu\text{-Cl})_2\text{LnCl}(\text{thf})_2(\mu\text{-Cl})_2\text{Ln}\dots$  chains.  $[\text{LnCl}_3(\text{thf})_4]$  have been isolated for Nd–Gd, and are monomeric seven-coordinate complexes, having pentagonal bipyramidal structures with two axial halides. Complexes with the nominal formula  $[\text{LnCl}_3(\text{thf})_{3.5}]$  are formed from Gd to Tm. These in fact have an ionic structure  $[\text{LnCl}_2(\text{thf})_5]^+ [\text{LnCl}_4(\text{thf})_2]^-$ , containing a seven-coordinate cation and octahedrally coordinated six-coordinate anion, both with trans-geometries. Ytterbium

forms a dimeric  $[\text{Cl}_2(\text{thf})_2\text{Yb}(\mu\text{-Cl})_2\text{Yb}(\text{thf})_2\text{Cl}_2]$ , whilst both ytterbium and lutetium form a monomeric octahedral *mer*- $[\text{LnCl}_3(\text{thf})_3]$  ( $\text{Ln} = \text{Yb}, \text{Lu}$ ) like scandium. Yttrium forms ‘ $\text{YCl}_3(\text{thf})_{3.5}$ ’ and  $\text{YCl}_3(\text{thf})_2$ , which has a chain structure with double chlorine bridges, having pentagonal bipyramidal coordination. Structures have been reported for many individual compounds and far-i.r. spectra of the complexes have been correlated with structural type.<sup>62</sup> Little is known about the bromides, though  $\text{Ln}(\text{THF})_4\text{Br}_3$  ( $\text{Ln} = \text{La}, \text{Ce}, \text{Nd}$ ) are<sup>63</sup> seven-coordinate pentagonal bipyramidal like the corresponding chlorides and  $\text{YbBr}_3(\text{thf})_3$  has *mer*-octahedral coordination. Iodide complexes  $\text{LnI}_3(\text{thf})_4$  [ $\text{Ln} = \text{La}, \text{Pr}$ ] and  $\text{LnI}_3(\text{thf})_{3.5}$  [ $\text{Ln} = \text{Nd}, \text{Sm}, \text{Gd}, \text{Dy}, \text{Er}, \text{Tm}, \text{Y}$ ] are prepared by reaction of the powdered metal and  $\text{I}_2$  in thf, followed by Soxhlet extraction. Only two structure types have been identified so far,  $\text{PrI}_3(\text{thf})_4$  again has a pentagonal bipyramidal structure, whilst  $\text{LnI}_3(\text{thf})_{3.5}$  [ $\text{Ln} = \text{Nd}, \text{Sm}, \text{Gd}, \text{Y}, \text{Yb}$ ] have the ‘ion pair’ structure  $[\text{LnI}_2(\text{thf})_5][\text{LnI}_4(\text{thf})_2]$  (pentagonal bipyramidal cation, octahedral anion) also familiar from the chlorides.<sup>64</sup>

Thiocyanate complexes have been synthesised by metathesis, from  $\text{LnCl}_3$  and KNCS in thf, followed by filtering off the KCl. The formula,  $\text{Ln}(\text{NCS})_3(\text{thf})_4$ , applies across the series, but falling into two types. The ytterbium compound is a monomer, having a pentagonal bipyramidal structure with two axial thiocyanates. For earlier lanthanides, the same stoichiometry  $\text{Ln}(\text{NCS})_3(\text{thf})_4$  obtains, but there is association by  $\text{Ln}\cdots\text{SNC-Ln}$  bridges so lanthanides are in eight-coordinate square-antiprismatic coordination. Ln–S interactions are in region 3.10 Å (Nd) to 3.26 Å (Er), increasing in length as Ln gets smaller suggesting that the interaction weakens as steric crowding increases. These compounds have been obtained for all Ln from Pr to Er.<sup>65</sup> A few nitrate complexes,  $[\text{Pr}(\text{thf})_4(\text{NO}_3)_3]$  and  $[\text{Ln}(\text{thf})_3(\text{NO}_3)_3]$  ( $\text{Ln} = \text{Ho}, \text{Yb}$ ) have been reported. Some complexes of multidentate ethers exist, such as  $[\text{LnCl}_3(\text{dme})_2]$ , a series made of two families,  $[\text{LnCl}_3(\text{dme})_2]_2$ , dimers with the structure  $[\text{Cl}_2(\text{dme})_2\text{Ln}(\mu\text{-Cl})_2\text{LnCl}_2(\text{dme})_2]$  ( $\text{Ln} = \text{La-Nd}$ ), and monomeric  $[\text{LnCl}_3(\text{dme})_2]$  (Nd–Lu).<sup>66</sup>

Among dimethyl sulfoxide complexes of lanthanide nitrates; early lanthanide nitrates form 10-coordinate  $\text{Ln}(\text{DMSO})_4(\text{NO}_3)_3$  ( $\text{Ln} = \text{La-Gd}$ ) while the heavier metals form  $\text{Ln}(\text{DMSO})_3(\text{NO}_3)_3$  ( $\text{Ln} = \text{Tb-Lu}, \text{Y}$ ). Studies of these complexes in solution indicate that the coordination number depends on the size of the lanthanide, with coordination numbers of 10 for lanthanum, decreasing to eight for Yb–Lu and also upon the DMSO concentration. A similar decrease was found for perchlorate complexes in solution; solid  $\text{Ln}(\text{DMSO})_8(\text{ClO}_4)_3$  compounds, where the perchlorate does not coordinate, have been isolated.<sup>67</sup> The EXAFS spectra of  $[\text{Ln}(\text{dmsO})_8](\text{CF}_3\text{SO}_3)_3$  in both the solid state and in dmsO solution are very similar, indicating the same coordination geometry in both. Similar pyridine *N*-oxide complexes have been made; with  $\text{Ln}(\text{pyO})_8(\text{ClO}_4)_3$  there is a change in coordination geometry of the  $\text{Ln}(\text{pyO})_8$  moiety with increasing ionic

**Figure 13** The structure of the  $\text{La}(\text{pyO})_8^{3+}$  ion

radius of the lanthanide, from square antiprismatic (Nd) to one intermediate between square antiprismatic and dodecahedral for the lanthanum compound (Figure 13).

### 3.7.5 Complexes of $\beta$ -Diketones<sup>68</sup>

A wide variety of important complexes of *Diketones* (see *Diketones*),  $\text{Ln}(\text{R}^1\text{COCHCOR}^2)_3$  has been synthesized and studied extensively. They came into prominence as *NMR Shift Reagents* in the early 1970s, but have subsequently found applications as precursors for high-temperature superconductors and chemical vapour deposition agents. The acetylacetonates (acac;  $\text{R} = \text{Me}$ ) can be readily made from a lanthanide salt and the diketone with sodium hydroxide in a solvent such as methanol. They crystallize as hydrates, generally containing eight-coordinate  $\text{Ln}(\text{acac})_3(\text{H}_2\text{O})_2$  (La–Ho, Y) (Figure 14) or seven-coordinate  $\text{Ln}(\text{acac})_3(\text{H}_2\text{O})$  (e.g. Yb) molecules. The dihydrate of gadolinium is, however, reported to be a dimer. Some tri- and tetrahydrates are known, but these contain lattice water in addition to  $\text{Ln}(\text{acac})_3(\text{H}_2\text{O})_2$  species (e.g. Eu, Ho). These water molecules can be hard to remove, and more sophisticated synthetic routes to  $\beta$ -diketonates in general begin with convenient starting materials like the oxides. The anhydrous acetylacetonates are not well defined, unlike the corresponding monomeric  $\text{M}(\text{acac})_3$  complexes formed by the d-block metals. The reasons for this are indicated in a careful study<sup>69</sup> of  $\text{Y}(\text{acac})_3$ , which found that reaction of  $[\text{Y}\{\text{N}(\text{SiMe}_3)_2\}_3]$  with Hacac gave hydrocarbon-soluble  $[\text{Y}(\text{acac})_3]_n$  (from NMR measurements,  $n \sim 4$ ). Inadvertent hydrolysis on attempted slow crystallisation led to  $[\text{Y}_4(\text{OH})_2(\text{acac})_{10}]$ , a molecule with a diamond shaped  $\text{Y}_4$  core, having  $\mu_4\text{-OH}$  groups above and below the plane, and each acac terminal, affording eight-coordinate Y. Controlled vacuum thermolysis ( $85^\circ\text{C}$ )

(a)

(b)

**Figure 14** (a) The structure of  $\text{Ho}(\text{PhCOCHCOPh})_3(\text{H}_2\text{O})$ . (b) The structure of  $\text{La}(\text{acac})_3(\text{H}_2\text{O})_2$

of  $[\text{Y}(\text{acac})_3(\text{H}_2\text{O})_3]$  gives a product that can be crystallised from benzene to form  $[\text{Y}_4(\text{OH})_2(\text{acac})_{10}] \cdot \text{C}_6\text{H}_6$ . It is believed that hydrogen-bonding between water molecules and acac oxygens in  $[\text{Y}(\text{acac})_3(\text{H}_2\text{O})_3]$  leads to the loss of acacH on thermolysis. In contrast, complexes of a bulkier ligand such as tmhd (dpm;  $\text{R} = t\text{-Bu}$ ) readily form anhydrous  $\text{Ln}(\text{tmhd})_3$  which sublime in vacuo at  $100\text{--}200^\circ\text{C}$  and are monomers in solution; they can be separated by gas chromatography. In the solid state they exist as dimers with seven-coordinate metals (La–Dy) and octahedral monomers (Dy–Lu, Y; trigonal prismatic coordination) which do hydrate readily (cf. capped trigonal prismatic  $\text{Dy}(\text{dpm})_3(\text{H}_2\text{O})$ ).

A similar pattern of decreasing coordination number with decreasing ionic radius is found in complexes of 2,2-dimethyl-6,6,7,7,8,8,8-heptafluorooctane-2,4-dione (fod). Thus  $\text{Pr}(\text{fod})_3 \cdot \text{H}_2\text{O}$  is in fact dimeric,  $[\text{Pr}_2(\text{fod})_6(\text{H}_2\text{O})] \cdot \text{H}_2\text{O}$ , with eight-coordination completed by a bridging water, whereas  $\text{Lu}(\text{fod})_3 \cdot \text{H}_2\text{O}$  is a seven-coordinate monomer. As prepared, the complexes are hydrates but can be dehydrated in vacuo and are volatile at  $180\text{--}260^\circ\text{C}$  (though they do

rehydrate avidly); trifluoro- and hexafluoroacetylacetonates are likewise generally obtained as hydrates which can be dehydrated in vacuo. Because the  $\text{Ln}(\text{diketonate})_3$  complexes are coordinatively unsaturated, they, as already noted, tend to complete their coordination sphere by forming adducts with Lewis bases, of which the hydrates have already been noted. For this reason, paramagnetic diketonates, especially some of the dpm and fod chelates, are of importance as NMR shift reagents (see Section ' $\beta$ -Diketones as NMR Shift Reagents'<sup>70–72</sup>).

In addition to the neutral tris complexes, anionic  $[\text{Ln}(\text{diketonate})_4]^-$  species have been isolated for some of the less bulky ligands, such as antiprismatic  $[\text{Eu}(\text{PhCOCHCOPh})_4]^-$ .

**$\beta$ -Diketones as NMR Shift Reagents<sup>70–72</sup>.** Paramagnetic lanthanide  $\beta$ -diketonate complexes produce shifts in the NMR spectra of Lewis base molecules capable of forming adducts with them and are thus often referred to as lanthanide shift reagents (LSR), although all paramagnetic lanthanide complexes can exhibit shifted resonances. The initial report (1969) concerned the ability of  $\text{Eu}(\text{dpm})_3\text{py}_2$  to induce considerable low-field shifts in the H spectrum of cholesterol; the magnitude of the proton shifts depended upon the distance of the proton from the site of coordination to the lanthanide ion. Subsequently it was realized that the diketonate complexes themselves were more effective than the pyridine adducts and that other lanthanide ions (e.g. Pr) could produce shifts in the opposite direction. Immense activity in this area resulted as the use of LSRs enabled simplification of the spectra of organic molecules (frequently to first order) without the use of high-frequency spectrometers. The spreading out of the spectrum and differential nature of the shifts removed degeneracies and overlaps while study of the shifts, particularly when more than one LSR was used, permitted spatial assignment of the protons (or other resonant nucleus) with concomitant structural information about the organic molecule.

Thus, to give but one example (Figure 15), the aromatic region of the proton NMR spectrum of benzyl alcohol is

**Figure 15** The proton NMR spectrum of benzyl alcohol in the presence of  $\text{Eu}(\text{dpm})_3$  (0.39 mol). (Reproduced by permission of The Royal Society of Chemistry from J.K.M. Sanders and D.H. Williams, *Chem. Commun.*, 1970, 422)

a singlet at 100 MHz, but on addition of  $\text{Eu}(\text{dpm})_3$ , which coordinates at the OH group, the aromatic protons are shifted by amounts varying with their distance from the coordination site and become amenable to first-order analysis.

The lanthanide induced shifts (LIS) arise from the interaction of the magnetic nucleus with the magnetic field of the paramagnetic lanthanide ion. This could arise via two mechanisms: either a 'pseudocontact' (dipolar) through-space fashion involving a dipole–dipole interaction, or by a 'contact' mechanism with delocalization of unpaired spin density from the lanthanide f-orbitals via the lanthanide–substrate bond on to the organic molecule; the former is more important.

**Adducts of Diketones.** Because of their involvement in NMR shift reagents, there has been considerable interest in the stoichiometry of the adducts formed between the diketonate complex and the Lewis base. Both 1:1 and 1:2 adducts are possible, the stoichiometry dependent upon the bulkiness of both the diketonate ligand and also upon that of the ligand. Since the species isolated in the solid state may not be the most abundant species in solution, complementary studies are necessary. Thus the  $\text{M}(\text{fod})_3$  chelates (Pr, Eu) have been found to form 1:1 and 1:2 adducts with a range of Lewis bases (even bulky ones like 2,4,6-Me<sub>3</sub>py) in solution. The bulkier dpm chelates give isolable 2:1 adducts with pyridine and propylamine (Eu), but with the bulkier 3-picoline, only a 1:1 complex is isolated (Lu). Careful studies of  $\text{Ho}(\text{dpm})_3$  in solution have only given evidence for 1:1 adducts with bulky ligands such as triphenylphosphine oxide, camphor, and borneol. Some of the adducts vaporize unchanged; thus  $\text{Ln}(\text{hfac})_3(\text{Bu}_3\text{PO})_2$  can be separated by gas chromatography. Adducts with polyethers have been studied as possible precursors for *Chemical Vapour Deposition* (see *Chemical Vapor Deposition*) as they often exhibit high volatility and good thermal stability. Thus  $\text{La}_2\text{O}_3$  and  $\text{Hhfac}$  react together with tetraglyme in hexane forming  $[\text{La}(\text{hfac})_3(\text{tetraglyme})]$ , an air-stable and volatile (95 °C,  $10^{-4}$  mm Hg) substance.

Crystal structures have been determined for many of the adducts.  $\text{Eu}(\text{acac})_3(\text{phen})$  is antiprismatic, but  $\text{Nd}(\text{ttaf})_3(\text{Ph}_3\text{PO})_2$ ,  $\text{Eu}(\text{dpm})_3(\text{py})_2$ , and  $\text{Ho}(\text{dpm})_3(4\text{-picoline})_2$  are dodecahedral. Of the seven-coordinate adducts,  $\text{Lu}(\text{dpm})_3(3\text{-picoline})$  is a side-face capped trigonal prism and  $\text{Eu}(\text{dpm})_3(\text{quinuclidine})$  a capped octahedron. With the tridentate ligand terpyridyl, nine-coordination is possible as in  $\text{Eu}(\text{dpm})_3(\text{terpy})$ ;  $\text{Pr}(\text{facam})_3(\text{DMF})_3$  is also nine-coordinate. What may be another case of nine-coordination are the acetylacetonate complexes  $\text{Ln}(\text{acac})_3(\text{Ph}_3\text{PO})_3$  (Ln = Nd, Sm, Eu, Tb, Dy, Ho).

The geometric differences between one structure and another are often small, and a similar comment may also be made about the energy differences between one structure and another (e.g. square antiprismatic–dodecahedron). The structure adopted for an adduct in the solid state may be different to the one adopted in solution. The assumption of time-averaged axial symmetry for the monoadducts in solution

in the interpretation of shifted NMR spectra seems frequently to be justified; however, study of bis adducts of substituted pyridines with  $\text{Ln}(\text{dpm})_3$  indicate biaxial magnetic anisotropy.

### 3.7.6 Carboxylates<sup>73</sup>

Carboxylate complexes of the lanthanides differ from those of many trivalent transition metals in that they do not adopt oxo-centered structures with  $\text{M}_3\text{O}$  cores. The hydrated acetates have a long history, with the first examples reported by Cleve in 1874; they can be synthesized by dissolving the oxides in acetic acid and the anhydrous compounds obtained by azeotropic distillation.

Anhydrous  $[\text{La}(\text{OAc})_3]$  has 10-coordinate La, involving both chelating and bridging acetates (the latter having one oxygen bound to two different lanthanum ions and the second oxygen just bound to one); the Ce analogue is isostructural. Both 9 and 10-coordinate praseodymium are found in  $\text{Pr}(\text{OAc})_3$ ; like  $\text{La}(\text{OAc})_3$ , this has a three-dimensional network structure, whereas for the later metals  $\text{Ln}(\text{CH}_3\text{COO})_3$  adopt chain structures. Holmium acetate adopts a structure shared with other  $\text{Ln}(\text{OAc})_3$  ( $\text{Ln} = \text{Sm} - \text{Er}$ , Y); Ho occupies two slightly different eight-coordinate sites, whilst  $\text{Ln}(\text{OAc})_3$  ( $\text{Ln} = \text{Tm} - \text{Lu}$ ) have the structure exemplified by  $\text{Lu}(\text{CH}_3\text{COO})_3$ , in which Lu is seven-coordinate. On heating, both these structures change to the six-coordinate  $\text{Sc}(\text{CH}_3\text{COO})_3$  structure, this drop in coordination number being accompanied by an acetate group switching to a symmetrical bridging mode.<sup>74</sup>

Among the hydrated lanthanide acetates, mono- and sesquihydrates are found for the early metals (La–Nd); the heavier metals (from Nd) tend towards tetrahydrates, but some trihydrates are known (e.g. Eu, Tm) though for any given lanthanide there may be two or more phases with nearly equal stabilities under ambient conditions. The sesquihydrates  $[\text{Ln}(\text{CH}_3\text{COO})_3 \cdot 1.5\text{H}_2\text{O}]$  ( $\text{Ln} = \text{La} - \text{Pr}$ ) have structures with acetate-bridged chains cross-linked by further acetate bridges; the lanthanides being 9 and 10-coordinated by bridging and chelating acetates. Monohydrates  $[\text{Ln}(\text{CH}_3\text{COO})_3 \cdot \text{H}_2\text{O}]$  ( $\text{Ln} = \text{Ce} - \text{Nd}$ ) have one-dimensional polymeric structures with acetate bridges, the lanthanides being 9-coordinate in this case, whilst the tetrahydrates  $[\text{Ln}(\text{CH}_3\text{COO})_3 \cdot 4\text{H}_2\text{O}]$  ( $\text{Ln} = \text{Sm} - \text{Lu}$ ) are acetate-bridged dimers, the lanthanides again being 9-coordinate. The bridging acetate groups in these compounds are often asymmetric, featuring one oxygen being bound to two lanthanide ions and the other oxygen bound to one lanthanide (this mode of bonding is common in lanthanide carboxylates). Among other carboxylates,  $\text{Pr}(\text{C}_3\text{H}_7\text{COO})_3 \cdot 3\text{H}_2\text{O}$  contains two distinctly different praseodymium sites. Each Pr is coordinated by four bidentate bridging carboxylates; additionally one is bound to three water molecules, the other is additionally bound to two bidentate propionates.  $\text{Nd}(\text{C}_3\text{H}_7\text{COO})_3(\text{H}_2\text{O})$  has a zigzag chain structure containing 9-coordinate neodymium in capped

square-antiprismatic coordination, there being two different neodymium sites. One neodymium is bound to four bridging tridentate carboxylates and one bridging bidentate group, as well as to two waters; the other neodymium is coordinated to four bridging tridentate carboxylates, one bridging bidentate carboxylate, and one chelating carboxylate.  $[\text{Ln}(\text{CF}_3\text{COO})_3 \cdot 3\text{H}_2\text{O}]$  ( $\text{Ln} = \text{La}, \text{Ce}$ ) are two-dimensional polymers containing eight-coordinate lanthanides, whilst  $[\text{Ln}(\text{CF}_3\text{COO})_3 \cdot 3\text{H}_2\text{O}]$  ( $\text{Ln} = \text{Pr} - \text{Lu}$ ) have seven-coordinate lanthanides in dimeric units with four bridging carboxylates.  $[\text{La}(\text{CCl}_3\text{COO})_3 \cdot 5\text{H}_2\text{O}]$  and  $[\text{Ce}(\text{CCl}_3\text{COO})_3 \cdot 3\text{H}_2\text{O}]$  are linear one-dimensional polymers with nine and eight-coordinate lanthanides respectively.  $[\text{Ln}(\text{CCl}_3\text{COO})_3 \cdot 2\text{H}_2\text{O}]$  ( $\text{Ln} = \text{Pr} - \text{Lu}$ ) are also linear polymers with a bridging water molecule rather than just carboxylate bridges. In these compounds the carboxylate groups act as bridging bidentate ligands or as terminal monodentate groups. Anhydrous europium methacrylate,  $[\text{Eu}(\text{H}_2\text{C}=\text{C}(\text{Me})\text{CO}_2)_3]$ , has a chain structure in which Eu is eight-coordinate, one carboxylate acting as a bidentate bridging ligand and the other two also bridging, but with one oxygen bound to two europiums, the familiar chelate-bridging mode. Both this compound and the acrylates  $[\text{Ln}(\text{H}_2\text{C}=\text{CHCO}_2)_3]$  ( $\text{Ln} = \text{Eu}, \text{Tb}$ ) undergo radical-induced polymerisation.

Carbonate complexes are increasingly studied because of their importance in mobilising the actinides in the environment; lanthanide complexes are nonradioactive models for the later actinides. The first mononuclear lanthanide carbonate complex to be structurally characterised was  $[\text{N}(\text{CH}_2)_3]_5[\text{Nd}(\text{CO}_3)_4]$ . On the other hand,  $[\text{Co}(\text{NH}_3)_6][\text{Sm}(\text{CO}_3)_3(\text{H}_2\text{O})] \cdot 4\text{H}_2\text{O}$  has anions linked in a zigzag chain structure with  $\mu - \eta^2 - \eta^1$  carbonate bridges affording nine-coordinate samarium. Similar bridges are found in the one-dimensional chains in  $[\text{Co}(\text{NH}_3)_6][\text{K}_2(\text{H}_2\text{O})_{10}][\text{Nd}_2(\text{CO}_3)_8]_2 \cdot 20\text{H}_2\text{O}$ , formed on mixing solutions of  $[\text{Co}(\text{NH}_3)_6]\text{Cl}_3$ ,  $\text{Nd}(\text{NO}_3)_3$  and  $\text{K}_2\text{CO}_3$ .

The oxalates are very insoluble, affording quantitative precipitation of the lanthanide, a fact made use of in traditional quantitative analysis; on ignition, they are obtained as the oxide, the weighing form. In the solid state, structures show eight-coordinate in the hexahydrates and nine-coordinate in the nonahydrates such as  $\text{Nd}_2(\text{C}_2\text{O}_4)_3 \cdot 9\text{H}_2\text{O}$ .

Structures of the dialkylcarbamates  $[\text{Ln}_4(\text{O}_2\text{CNPr}^i)_{12}]$  ( $\text{Ln} = \text{Nd}, \text{Gd}, \text{Ho}, \text{Yb}$ ) indicate a steady contraction in Ln–O distances, averaging 14%, across the lanthanide series.

### 3.7.7 Nitrate Complexes

Nitrate complexes are of historical importance for their role in separation of the early lanthanides by fractional crystallization, when magnesium double nitrates,  $\text{Mg}_3\text{Ln}_2(\text{NO}_3)_{12} \cdot 24\text{H}_2\text{O}$ , were used. These complexes contain 12-coordinate  $[\text{Ln}(\text{NO}_3)_6]^{3-}$  groups, also found in some crown ether complexes. Other nitrate complexes characterized include 10-coordinate  $[\text{Ln}(\text{NO}_3)_5]^{2-}$ , as salts with counterions

like  $\text{Ph}_4\text{As}$  and  $\text{Me}_4\text{N}$ . Both these types of complex are characterized across the lanthanide series.

### 3.7.8 Complexes of Crown Ethers<sup>75,76</sup>

Crown ether (*see Crown Ethers*) complexes represent a very important area of lanthanide coordination chemistry that has undergone considerable development in recent years (*see Crown Ethers*). In contrast to the alkali metals, the lanthanides do not form such complexes readily in aqueous media, owing to the considerable hydration energy of the lanthanide ion, but are readily synthesized by operating in nonaqueous solvents. Complexes are obtained both with and without direct lanthanide-crown ether bonds as when  $[\text{Ln}(\text{NO}_3)_3(\text{H}_2\text{O})_3]$  is encapsulated by 18-crown-6. The choice is determined by the match between the size of the central cavity in the crown ether ring and the size of the lanthanide ion. Many of the studies have been made with lanthanide nitrate complexes, with the concomitant consequence of high coordination numbers in the resulting complexes on account of the proclivity for bidentate nitrate coordination. Thus 12-coordination is found in  $\text{La}(\text{NO}_3)_3(18\text{-crown-6})$  (Figure 16), 11-coordination in  $\text{Eu}(\text{NO}_3)_3(15\text{-crown-5})$ , and 10-coordination in  $\text{Eu}(\text{NO}_3)_3(12\text{-crown-4})$ .

In addition to the 1:1 complexes, some other stoichiometries have been obtained; thus  $\text{Nd}(18\text{-crown-6})_{0.75}(\text{NO}_3)_3$  is actually  $[\text{Nd}(18\text{-crown-6})(\text{NO}_3)_2]_3[\text{Nd}(\text{NO}_3)_6]$  with 10-coordination in the cation and 12-coordination in the anion.

The first crown ether complexes to be made were usually with lanthanide nitrates; when crown ethers complex with lanthanide nitrates, the two ligands generally combine to saturate the coordination sphere, but since chloride is a

monodentate ligand, coordinative saturation is not always achieved that way and indeed chlorides are frequently displaced from the coordination sphere by water. Thus 12-crown-4 tends to give complexes of the type  $[\text{Ln}(\text{H}_2\text{O})_5(12\text{-C-4})]\text{Cl}_3 \cdot 2\text{H}_2\text{O}$  (Ln e.g. Er) and  $[\text{LnCl}_2(\text{H}_2\text{O})_2(12\text{-C-4})]\text{Cl} \cdot 2\text{H}_2\text{O}$  (Ln e.g. Nd) but coordinating ability is affected by the presence of water and other solvents. The crown ether does not coordinate to the lanthanide at all in  $[\text{Lu}(\text{H}_2\text{O})_8] 1.5(12\text{-C-4}) \cdot 2\text{H}_2\text{O}$ , instead forming hydrogen bonds to coordinated water molecules. With the larger lanthanum ion,  $[\text{LaCl}_3(12\text{-crown-4})(\text{MeOH})]$  is eight-coordinate, owing to a molecule of solvent coordinating. 18-crown-6 forms two series of complexes with lanthanide chlorides  $[\text{LnCl}(\text{H}_2\text{O})_2(18\text{-crown-6})]\text{Cl}_2 \cdot 2\text{H}_2\text{O}$  (Ln = Pr–Tb) and  $[\text{LnCl}_2(\text{H}_2\text{O})(18\text{-crown-6})]\text{Cl} \cdot 2\text{H}_2\text{O}$  (Ln = La, Ce) although, depending upon conditions,  $[\text{LnCl}_3(18\text{-crown-6})]$  can also be made. Its inability to form complexes with the chlorides of the smaller lanthanides is ascribed to a lack of flexibility found in polyethylene glycols, which can. By modifying conditions, different complexes can be isolated; thus in MeCN/MeOH, neodymium chloride and 15-crown-5 react to afford complexes where  $[\text{Nd}(\text{H}_2\text{O})_9]^{3+}$  and  $[\text{NdCl}_2(\text{H}_2\text{O})_6]^+$  ions are hydrogen-bonded to the crown ether, without direct lanthanide–crown ether bonding. However, by electrocrystallization the anhydrous eight-coordinate complex  $\text{Nd}(15\text{-crown-5})\text{Cl}_3$  with neodymium–crown ether bonding is obtained (Figure 17).

Unusually, chloride is found in the first coordination sphere of lanthanum as well as nitrate in the serendipitously discovered mixed anion complexes  $[\text{LaCl}_2(\text{NO}_3)(12\text{-crown-4})]_2$  and  $[\text{LaCl}_2(\text{NO}_3)(18\text{-crown-6})]$ . A few complexes have been reported with other halides, such as  $[\text{SmI}_3(\text{dibenzo-18-crown-6})]$  (tricapped trigonal prismatic) and  $[\text{LaBr}_3(12\text{-crown-4})(\text{acetone})]$  (distorted square antiprismatic). Lanthanide thiocyanate complexes of crown ethers are now starting to be studied. Several thiocyanate complexes of the

Figure 16 The structure of  $\text{La}(\text{NO}_3)_3(18\text{-crown-6})$

Figure 17 The structure of  $\text{NdCl}_3(15\text{-crown-5})$

tetradentate 13-crown-4 have been isolated in  $[\text{Ln}(\text{NCS})_3(13\text{-crown-4})(\text{H}_2\text{O})_2]$  ( $\text{Ln} = \text{La}, \text{Pr} \text{--} \text{Tb}, \text{Er} \text{--} \text{Yb}$ ) whilst lanthanum is 10-coordinate in  $[\text{La}(\text{NCS})_3(18\text{-crown-6})(\text{dmf})]$ . In the compounds  $[\text{Ln}(\text{dibenzylidiazia-18-crown-6})(\text{NCS})_3]$  ( $\text{Ln} = \text{Ce}, \text{Nd}, \text{Eu}$ ), the lanthanide is bound to two nitrogens and four oxygens in the crown ether as well as three N-bonded thiocyanates. The  $\text{CeN}_3(\text{NCS})$  moiety exists as a trigonal planar arrangement at the centre of the macrocycle cavity with the trigonal plane perpendicular to the plane of the macrocycle. Steric factors can be important in complexation. Thus only the lighter, larger, lanthanides form stable complexes with 18-crown-6. Small crowns such as 12-crown-4 give 2:1 complexes with lanthanide perchlorates, although these are not obtained with lanthanide nitrates where the anion can readily coordinate.

Crown ethers have been used to stabilise alkyl complexes, in the form of  $[\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(12\text{-crown-4})]$  ( $\text{Ln} = \text{Sc}, \text{Y}, \text{Sm}, \text{Gd}, \text{Tb}, \text{Dy}, \text{Ho}, \text{Er}, \text{Tm}, \text{Yb}, \text{Lu}$ ); structures of the Y and Lu complexes show facial coordination of the crown ether to the neutral lanthanide trialkyl unit. The cationic species  $[\text{Ln}(\text{CH}_2\text{SiMe}_3)_2(\text{CE})(\text{thf})_n]^+ [\text{B}(\text{C}_6\text{X}_5)_3(\text{CH}_2\text{SiMe}_3)]^-$  ( $\text{CE} = [12]\text{-crown-4}, n = 1$ ;  $\text{CE} = [15]\text{-crown-5}, [18]\text{-crown-6}, n = 0$ ) have also been made.

Comparative studies between crown ethers and the noncyclic glymes (linear polyethers) suggest that glyme complexes are favoured, the chelate effect is thus more important than the macrocyclic effect. The ability of polyethylene glycols and glymes to wrap themselves round a lanthanide ion irrespective of size, and to accommodate water molecules and other small ligands (e.g. anions) more easily, makes them more flexible coordinating agents than crown ethers and giving a more favorable enthalpy change. Solubility effects may play a part too! The factors affecting the complexes formed by  $\text{LnX}_3$ ,  $\text{Ln}(\text{NCS})_3$  and  $\text{Ln}(\text{NO}_3)_3$  with polyethylene glycols have been examined; the chain length is the main factor controlling the coordination sphere and thus the number of additional inner-sphere ligands present. Pentaethylene glycol forms two series of nine-coordinate complexes with lanthanide chlorides,  $[\text{LnCl}_2(\text{H}_2\text{O})(\text{EO5})]\text{Cl} \cdot 2\text{H}_2\text{O}$  ( $\text{Ln} = \text{La} \text{--} \text{Pr}$ ) and  $[\text{Ln}(\text{H}_2\text{O})_3(\text{EO5})]\text{Cl}_3 \cdot \text{H}_2\text{O}$  ( $\text{Ln} = \text{Sm} \text{--} \text{Lu}, \text{Y}$ ).  $[\text{Ln}(\text{EO3})_3]\text{Cl}_3$  ( $\text{Ln} = \text{Pr}, \text{Nd}$ ) are nine-coordinate, as are the lanthanides in  $[\text{Ln}(\text{EO2})_3](\text{ClO}_4)_3 \cdot 3\text{H}_2\text{O}$  ( $\text{Ln} = \text{Nd}, \text{Ho}$ ), whilst the lanthanide is 11-coordinate in  $[\text{Nd}(\text{EO4})(\text{NO}_3)_3]$ . Cerium is nine-coordinate in  $[\text{Ce}(\text{NCS})_3(\text{EO4})(\text{H}_2\text{O})]$ .

Other significant complexes of this type, containing one or more lanthanides, are formed by calixarenes (see *Calixarenes*).<sup>77,78</sup> Much of this work has been prompted by their potential in separating lanthanides from uranium and other metals. A calixarene ligand with two amide substituents has been synthesised as an extractant for lanthanides; dimeric Sm and Eu and monomeric Lu complexes have been prepared. Another calixarene, with four phosphine oxides attached, has been fixed to silica particles and the resulting system has been found to give very efficient extraction of  $\text{Eu}^{3+}$  and  $\text{Ce}^{3+}$  from simulated waste. A calix[4]arene complex of  $\text{Gd}^{3+}$  binds

noncovalently to human serum albumin and is a potential MRI contrast agent.

### 3.7.9 Halide Complexes<sup>79</sup>

Complexes with all the halides have been prepared, but the chlorides and particularly the fluorides are most stable and best characterized. The fluorides  $\text{ALnF}_4$ ,  $\text{A}_2\text{LnF}_5$ , and  $\text{A}_3\text{LnF}_6$  are known ( $\text{A} = \text{alkali metal}$ ). The tetrafluoro complexes  $\text{NaLnF}_4$  exist in two phases, the high-temperature form having eight-coordinate lanthanide (fluorite structure) while tricapped trigonal prismatic nine-coordination is found in the low-temperature form. Some hexafluoro complexes have the cryolite structure.

Six-coordinate chloride complexes  $\text{Cs}_2\text{NaLnCl}_6$  with the cubic elpasolite structure have been made by fusion; the  $\text{Ln}^{3+}$  ions on the highly symmetric cubic sites exhibit very weak f–f transitions in their electronic spectra.  $(\text{NH}_4)_3\text{YCl}_6$  and  $\text{A}_3\text{LnCl}_6$  ( $\text{Ln} = \text{Tb} \text{--} \text{Lu}, \text{Y}$ ) can be made similarly. Other hygroscopic complexes of the type  $(\text{Ph}_3\text{PH})_3\text{LnX}_6$  and  $(\text{pyH})_3\text{LnX}_6$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) can be made by solution methods; the iodides are unusual and rather unstable. Octahedral  $\text{YbCl}_6^{3-}$  units are found in  $(\text{MeNH}_3)_4\text{YbCl}_7$ . Compounds  $\text{M}_2\text{LnCl}_5$  contain chains based on  $\text{LnCl}_6$  octahedra sharing *cis* corners (X-ray for  $\text{Cs}_2\text{DyCl}_5$ ;  $\text{Ln} = \text{Y}$ , heavy lanthanide). A different type of shared octahedra is found in a number of compounds  $\text{M}_3\text{Ln}_2\text{X}_9$ , where face sharing of octahedra obtains. A number of chlorides have been made ( $\text{M} = \text{K}$  or  $\text{Cs}$ ) as well as several bromides and iodides such as  $\text{Cs}_3\text{Y}_2\text{X}_9$  and  $\text{Cs}_3\text{Er}_2\text{I}_9$ .

### 3.7.10 Complexes of N-Donor Ligands<sup>4,5</sup>

Although pyridine and other amine-type ligands form adducts with lanthanide diketonates, few other lanthanide complexes have been made. However, the first homoleptic lanthanide ammine complexes,  $[\text{Yb}(\text{NH}_3)_8][\text{Cu}(\text{S}_4)_2] \cdot \text{NH}_3$ ,  $[\text{Yb}(\text{NH}_3)_8][\text{Ag}(\text{S}_4)_2] \cdot 2\text{NH}_3$ , and  $[\text{La}(\text{NH}_3)_9][\text{Cu}(\text{S}_4)_2]$ , have been synthesised by reactions in aqueous ammonia.<sup>80</sup>

Direct reaction of the lanthanide halides with pyridine gives pyridine complexes of the lanthanides, with the synthesis of  $[\text{YCl}_3\text{py}_4]$  and  $[\text{LnCl}_3\text{py}_4] \cdot 0.5\text{py}$  ( $\text{Ln} = \text{La}, \text{Er}$ ). These all have pentagonal bipyramidal structures, with two chlorines occupying the axial positions.<sup>81</sup>  $[\text{MI}_3\text{py}_4]$  ( $\text{M} = \text{Ce}, \text{Nd}$ ) have also been reported. Various complexes of *N*-methylimidazole (*N*-Meim) have been made,  $[\text{SmI}_3(\text{thf})_3]$  reacts with *N*-Meim forming square-antiprismatic  $[\text{Sm}(\text{Meim})_8]\text{I}_3$ , whilst  $[\text{YX}_2(\text{N-Meim})_5]^+\text{X}^-$ , ( $\text{X} = \text{Cl}, \text{Br}$ );  $[\text{YCl}_2(\text{N-Meim})_5]^+[\text{YCl}_4(\text{N-Meim})_2]^-$  and  $[\text{Ce}(\text{NO}_3)_3(\text{N-Meim})_4]$  have also been prepared.

A number of MeCN complexes  $[\text{Ln}(\text{MeCN})_n]\text{X}_3$  have been made, with routes including the reaction of  $\text{LnCl}_3$  with  $\text{AlCl}_3$  in MeCN; reaction of the labile complexes  $\text{La}(\text{OSO})_x(\text{AsF}_6)_3$  with MeCN; and ultrasonication of mixtures of the lanthanide metal with  $\text{AlCl}_3$  and MeCN in  $\text{C}_2\text{Cl}_6$ .

Structures of  $[\text{La}(\text{MeCN})_9] (\text{AsF}_6)_3 \cdot \text{MeCN}$ ;  $[\text{Sm}(\text{MeCN})_9] (\text{AsF}_6)_3 \cdot 3\text{MeCN}$ ;  $[\text{Ln}(\text{MeCN})_9] (\text{AlCl}_4)_3 \cdot \text{MeCN}$  ( $\text{Ln} = \text{Pr}, \text{Sm}$ ) and  $[\text{Yb}(\text{MeCN})_8] (\text{AlCl}_4)_3$  are all known, the  $[\text{Ln}(\text{MeCN})_9]^{3+}$  ions having the familiar tricapped trigonal prismatic coordination of the lanthanide.<sup>82</sup>

The best studied monodentate N-donor is the thiocyanate ion, recent extensive studies<sup>83</sup> by Japanese workers showing it to participate in complexes with an interesting variety of stoichiometry and coordination geometry dependent upon counterion, solvent, and so on. They comprise  $(\text{Bu}_4\text{N})_3[\text{M}(\text{NCS})_6]$  ( $\text{M} = \text{Y}, \text{Pr} - \text{Yb}$ ) and  $(\text{Et}_4\text{N})_3[\text{M}(\text{NCS})_6] \cdot \text{benzene}$  ( $\text{M} = \text{Er}, \text{Yb}$ ) with octahedrally coordinated lanthanide;  $(\text{Et}_4\text{N})_4[\text{M}(\text{NCS})_7] \cdot \text{benzene}$  ( $\text{M} = \text{La}, \text{Pr}$  with capped trigonal prismatic geometry) and  $(\text{Me}_4\text{N})_4[\text{M}(\text{NCS})_7]$ , ( $\text{M} = \text{Dy}, \text{Er}, \text{Yb}$ ; pentagonal bipyramidal coordination);  $(\text{Et}_4\text{N})[\text{M}(\text{NCS})_4(\text{H}_2\text{O})_4]$  ( $\text{M} = \text{Nd}, \text{Eu}$ ) and  $(\text{Me}_4\text{N})_3[\text{M}(\text{NCS})_6(\text{MeOH})(\text{H}_2\text{O})]$  ( $\text{M} = \text{La} - \text{Dy}, \text{Er}$ ), all square antiprismatic;  $(\text{Et}_4\text{N})_4[\text{M}(\text{NCS})_7(\text{H}_2\text{O})]$  ( $\text{M} = \text{La} - \text{Nd}, \text{Dy}, \text{Er}$ ; cubic); and  $(\text{Me}_4\text{N})_5[\text{M}(\text{NCS})_8] \cdot \text{benzene}$  ( $\text{M} = \text{La} - \text{Dy}$ ), intermediate between square antiprism and cubic.

A considerable number of complexes have been made using bidentate 1,10-phenanthroline, 2,2'-bipyridyl and similar ligands. Usually (but not invariably) phen and bipy form complexes with similar formulae and structures. Reaction of the hydrated lanthanide nitrate and the ligand in ethanol give complexes  $\text{LnL}_2(\text{NO}_3)_3$  ( $\text{L} = \text{phen}, \text{bipy}$ ), which have been studied in more detail than the others; both series are isomorphous throughout,<sup>84</sup> so all appear to possess 10-coordinate structures (Figure 18) with all nitrates present as coordinated bidentate groups (X-ray diffraction,  $\text{L} = \text{bipy}$ ,  $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}, \text{Eu}, \text{Lu}, \text{Y}$ ;  $\text{L} = \text{phen}$ ,  $\text{Ln} = \text{La},$

Figure 18 The structure of  $\text{La}(\text{phen})_2(\text{NO}_3)_3$

$\text{Pr}, \text{Nd}, \text{Sm}, \text{Eu}, \text{Gd}, \text{Dy}, \text{Lu}, \text{Y}$ ) with a geometry approximating to a bicapped dodecahedron.<sup>85</sup> In the solid state, the individual complex molecules of  $[\text{Ln}(\text{phen})_2(\text{NO}_3)_3]$  associate by  $\pi - \pi$  stacking into one-dimensional chains which themselves arrange into pseudo 1D close-packed patterns. Several tris complexes,  $\text{M}(\text{bipy})_3(\text{NO}_3)_3$ , have been synthesised in a water-ethanol mixture, the Nd complex being shown to be  $\text{Nd}(\text{bipy})_2(\text{NO}_3)_3 \cdot \text{bipy}$ . In the presence of 15-crown-5, lanthanum nitrate reacts with bipy in  $\text{MeOH} - \text{MeCN}$  forming  $[\text{La}(\text{bipy})(\text{NO}_3)_3(\text{H}_2\text{O})_2(\text{MeOH})] \cdot 15\text{-crown-5}$ , which has 11-coordinate lanthanum. The presence of the coordinated MeOH molecule supplies a fifth hydrogen atom so that hydrogen bonds can be formed to all the crown ether oxygens. In another synthesis in the presence of a crown ether, a 10-coordinate complex,  $[\text{La}(\text{bipy})(\text{NO}_3)_3(\text{H}_2\text{O})_2] \cdot \text{benzo-15-crown-5}$ , is obtained. A complex of composition  $\text{La}(\text{phen})_4(\text{NO}_3)_3 \cdot 3\text{H}_2\text{O}$  is in fact  $[\text{La}(\text{phen})_2(\text{H}_2\text{O})_2(\text{NO}_3)_2] \cdot \text{NO}_3 \cdot 2\text{phen} \cdot \text{H}_2\text{O}$  with intermolecular  $\pi - \pi$  stacking (a phenomenon which is quite common in phen complexes of the lanthanides).

An extremely wide range of both 1:1 and 2:1 complexes of lanthanide chlorides with bipy and phen have lately received detailed and extensive crystallographic study.<sup>86</sup> For the 1:1 complexes of early lanthanides ( $\text{La}, \text{Pr}$ ), the tendency seems to be for the formation of neutral complexes containing all available chloride ions, often binuclear in composition, usually containing at least two solvent molecules per lanthanide. By later in the series, mononuclear species tend to become more normal, and chloride ions are often excluded from the coordination sphere by solvent molecules. In the case of the 2:1 complexes, nine-coordination is possible at the start of the series in  $[(\text{bipy})_2\text{Ln}(\text{OH}_2)_4\text{Cl}]\text{Cl}_2 \cdot 2\text{H}_2\text{O}$ , whilst by the end of the series ytterbium is seven-coordinate in  $[(\text{bipy})_2\text{YbCl}_3]$ . M-N bond lengths contract from 2.724–2.787 Å in the lanthanum compound to 2.439–2.479 Å in the ytterbium compound. The situation has been described as ‘a multidimensional jigsaw puzzle which still requires a great deal of work for its complete description’. Bipyridyl complexes of known structure include  $[(\text{bipy})_2\text{Cl}_2\text{La}(\mu\text{-Cl})_2\text{LaCl}_2(\text{bipy})_2] \cdot \text{EtOH}$ ,  $[(\text{bipy})_2\text{Pr}(\text{OH}_2)\text{Cl}_3] \cdot 0.5\text{EtOH}$ ,  $[(\text{bipy})_2\text{Ln}(\text{OH}_2)\text{Cl}_3] \cdot \text{EtOH}$  ( $\text{Ln} = \text{Nd}, \text{Eu}$ )  $[(\text{bipy})\text{Ln}(\text{OH}_2)_6]\text{Cl}_3$  ( $\text{Ln} = \text{Ho} - \text{Lu}, \text{Y}$ ), and  $[(\text{bipy})_2\text{YbCl}_3]$ ; phen complexes include  $[(\text{phen})_2\text{Ln}(\text{OH}_2)\text{Cl}_3] \cdot \text{MeOH}$  ( $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}, \text{Eu}$ ),  $[(\text{phen})_2\text{La}(\text{OH}_2)_5]\text{Cl}_3 \cdot \text{phen} \cdot 4\text{H}_2\text{O}$  and  $[(\text{phen})_2\text{Lu}(\text{OH}_2)_4]\text{Cl}_3 \cdot 2\text{H}_2\text{O}$ . An apparent 3:1 complex,  $\text{La}(\text{phen})_3\text{Cl}_3 \cdot 9\text{H}_2\text{O}$  has been shown to be  $[\text{La}(\text{phen})_2(\text{OH}_2)_5]\text{Cl}_3 \cdot 4\text{H}_2\text{O} \cdot \text{phen}$ ; the ability of phen molecules to be held in lattice sites by  $\pi - \pi$  interaction with coordinated phenanthroline molecules is not uncommonly encountered. Complexes with lanthanide bromides do not seem to have received attention, but one iodide complex,  $[\text{CeI}_3(\text{bipy})_2(\text{py})] \cdot 5\text{py} \cdot \text{bipy}$  has been reported.

The thiocyanate complexes  $\text{Ln}(\text{phen})_3(\text{NCS})_3$  ( $\text{Ln} = \text{Pr}, \text{Nd}$ ) and  $\text{Pr}(\text{bipy})_3(\text{NCS})_3$  are all nine-coordinate monomers.<sup>85,87</sup> A considerable number of bipy (and phen) adducts of lanthanide dithiocarbamates  $[\text{Ln}(\text{S}_2\text{CNR}_2)_3(\text{L})]$

have been synthesised, usually by one-pot syntheses involving a lanthanide salt,  $\text{NaS}_2\text{CNR}_2$  and the neutral ligand. The interest here is in the potential of these compounds as precursors to lanthanide sulphides. Monomeric 8 coordinate structures are confirmed for  $[\text{Ln}(\text{S}_2\text{CNEt}_2)_3(\text{bipy})]$  ( $\text{Ln} = \text{Pr}, \text{Sm}, \text{Eu}, \text{Er}$ )<sup>85</sup> and  $[\text{Ln}(\text{S}_2\text{CNEt}_2)_3(\text{phen})]$  ( $\text{Ln} = \text{Sm}, \text{Eu}, \text{Yb}$ ).  $[\text{Eu}(\text{L})(\text{S}_2\text{PBU}_2)_3]$  ( $\text{L} = \text{phen}, \text{bipy}$ ) have also been made.

Carboxylate complexes are frequently dimeric. Thus  $\text{Lu}(\text{O}_2\text{CCH}_3)_3 \cdot (\text{phen}) \cdot \text{H}_2\text{O}$  is dinuclear  $[(\text{phen})(\text{CH}_3\text{COO})\text{Lu}(\mu\text{-O}_2\text{CCH}_3)_4\text{Lu}(\text{CH}_3\text{COO})(\text{phen})]$ . The terminal acetate groups are symmetrically bidentate; two of the bridging acetates are symmetrical, the other pair bridging in such a way that one of the two oxygens is bound to both lutetiums and the other is bound only to one lutetium. Similarly,  $\text{Ln}(\text{OAc})_3 \cdot \text{phen}$  ( $\text{Ln} = \text{Gd}, \text{Ce}$ ) are  $[(\text{AcO})(\text{phen})\text{Ln}(\mu\text{-OAc})_4\text{Ln}(\text{phen})(\text{OAc})]$  with two types of bridging acetate. The cerium compound gives a triplet EPR (see *Electron Paramagnetic Resonance*) spectrum at 4.2 K, showing an appreciable bridging interaction between the two ceriums ( $D = 0.21 \text{ cm}^{-1}$ ); magnetic measurements to low temperatures on both compounds confirm weak interactions between the two metal ions.  $[\text{Pr}(\text{O}_2\text{CCMe}_3)_3(\text{bipy})]_2$  has two bidentate bridging and two tridentate cyclic bridging carboxylates; praeosodymium is nine-coordinate.

The only complex with a non coordinating anion to be characterised fully is  $[\text{Ce}(\text{phen})_4(\text{MeCN})_2](\text{ClO}_4)_3 \cdot 3\text{MeCN}$ , which has 10-coordinate cerium in a bicapped square-antiprismatic geometry.

Another bidentate ligand whose complexes have been studied in some detail is 1,8-naphthyridine (naph) which, like nitrate, has a small bite angle and is similarly capable of affording high coordination numbers; two types of perchlorate complexes have been made,  $\text{M}(\text{naph})_6(\text{ClO}_4)_3$  ( $\text{M} = \text{La}-\text{Pr}$ ) and  $\text{M}(\text{naph})_5(\text{ClO}_4)_3$  ( $\text{M} = \text{Nd}-\text{Eu}$ ). The former complexes have 12-coordinate lanthanides, confirmed by diffraction methods for the praeosodymium complex. The change in stoichiometry is doubtless a manifestation of the lanthanide contraction.

A number of complexes of 1,2-diaminoethane have been made. Infrared evidence for the complexes  $\text{Ln}(\text{en})_4(\text{NO}_3)_3$  indicated the presence of coordinated nitrate for the earlier metals, so that the complexes were formulated  $[\text{Ln}(\text{en})_4(\text{NO}_3)](\text{NO}_3)_2$  ( $\text{La}-\text{Sm}$ ) and  $[\text{Ln}(\text{en})_4](\text{NO}_3)_3$  ( $\text{Eu}-\text{Lu}$ ). Other complexes isolated include perchlorates  $[\text{Ln}(\text{en})_4](\text{ClO}_4)_3$  ( $\text{Ln} = \text{La}-\text{Nd}$ ), chlorides,  $\text{Ln}(\text{en})_4\text{Cl}_3$ ,  $[\text{La}(\text{en})_4\text{Cl}]\text{In}_2\text{Te}_4$  and  $[\text{Y}(\text{en})_4](\text{SH})_{2.72}\text{I}_{0.28}$ , the latter two having nine- and eight- coordination respectively.

Complexes of the lanthanides with the rather similar terdentate ligands 2,2':6',2''-terpyridyl (terpy), 2,4,6-tris-2-pyridyl-1,3,5-triazine (tptz), 4-amino-bis(2,6-(2-pyridyl))-1,3,5-triazine (abptz), and related ligands have been studied in considerable detail and number, as these terdentate N-donor ligands are efficient in separating actinides from lanthanides selectively by solvent extraction, of obvious relevance to processing nuclear waste.

Reaction of aqueous lanthanide chlorides with alcoholic solutions of terpy affords complexes  $\text{Ln}(\text{terpy})\text{Cl}_3 \cdot x\text{H}_2\text{O}$  ( $x = 6-8$ ). They contain  $[\text{Ln}(\text{terpy})\text{Cl}(\text{H}_2\text{O})_n]^{2+}$  ions ( $\text{Ln} = \text{La}-\text{Nd}$ ,  $n = 5$ ;  $\text{Ln} = \text{Sm}-\text{Lu}$ ,  $n = 4$ ). Within these two families of cations, there are the expected contractions in bond length with increasing atomic number (and decreasing ionic radius). Thus on going from La to Nd in the series of  $[\text{Ln}(\text{terpy})\text{Cl}(\text{H}_2\text{O})_5]^{2+}$  ions, there are contractions in  $\text{Ln}-\text{Cl}$ , from 2.903 (2) to 2.855 (1) Å; in average  $\text{Ln}-\text{N}$  distance, from 2.688 to 2.616 Å; and in average  $\text{Ln}-\text{O}$  distance, from 2.561 to 2.505 Å. Similarly, in the  $[\text{Ln}(\text{terpy})\text{Cl}(\text{H}_2\text{O})_4]^{2+}$  ions, on passing from Sm to Lu, there are decreases in  $\text{Ln}-\text{Cl}$ , from 2.794 (2) to 2.665 (2) Å; in the average  $\text{Ln}-\text{N}$  distance, from 2.513 to 2.457 Å; and in average  $\text{Ln}-\text{O}$  distance, from 2.475 to 2.317 Å. There are two families of bromide complexes, nine-coordinate  $[\text{Ln}(\text{terpy})(\text{H}_2\text{O})_6]\text{Br}_3 \cdot \text{H}_2\text{O}$  ( $\text{Ln} = \text{La}-\text{Er}$ ) and eight-coordinate  $[\text{Ln}(\text{terpy})(\text{H}_2\text{O})_5]\text{Br}_3 \cdot 3\text{H}_2\text{O}$  ( $\text{Ln} = \text{TmLu}$ ) all isolated from water-ethanol mixtures. Unlike in the chlorides, there is no bromide in the coordination sphere, a reflection of the weaker  $\sigma$ -donor power of bromide (though no studies have been reported in nonaqueous solvents). A hydroxy-bridged dimeric species to be formed with the heavier lanthanides, but usually acidification converts it into the mononuclear complex. The dimers contain bridging hydroxy groups, not halides, again reflecting the decreasing coordinating power of bromide. Iodide complexes have been isolated using nonpolar solvents, thus terpy reacts with solutions of  $\text{LnI}_3$  in anhydrous pyridine forming eight-coordinate  $[\text{Ln}(\text{terpy})_2\text{I}_2]\text{I}$  ( $\text{Ln} = \text{Ce}, \text{Nd}$ ), whilst  $[\text{Ce}(\text{terpy})_2\text{I}_2]\text{I}$  crystallises from slightly damp solvents forming nine-coordinate  $[\text{Ce}(\text{terpy})_2\text{I}_2(\text{H}_2\text{O})]\text{I}$ . A comparison of structural data for  $[\text{Ce}(\text{terpy})_2\text{I}_2(\text{H}_2\text{O})]\text{I}$  and  $[\text{U}(\text{terpy})_2\text{I}_2(\text{py})]\text{I}$  indicates that the average U-N distance is shorter by about 0.05 Å, though on size grounds they would be expected to be very similar. This shortening may reflect a  $\pi$  back-bonding interaction between the 5f orbitals of uranium and the terpyridyl ligand which is absent in the lanthanide complex. Thiocyanate complexes  $[\text{Ln}(\text{terpy})_2(\text{NCS})_3]$  ( $\text{Ln} = \text{Pr}, \text{Nd}$ ), contain nine-coordinate lanthanides.<sup>87</sup>

Reaction of terpy with lanthanide perchlorates in MeCN affords  $[\text{La}(\text{terpy})_3](\text{ClO}_4)_3 \cdot 2\text{MeCN} \cdot 0.67\text{H}_2\text{O}$ ,  $[\text{Ln}(\text{terpy})_3](\text{ClO}_4)_3 \cdot \text{MeCN} \cdot \text{H}_2\text{O}$  ( $\text{Ln} = \text{Ce}, \text{Pr}, \text{Sm}, \text{Eu}$ ),  $[\text{Ln}(\text{terpy})_3](\text{ClO}_4)_3$  ( $\text{Eu}, \text{Lu}, \text{Y}$ ); all of these have nine-coordinate  $[\text{Ln}(\text{terpy})_3]^{3+}$  cations with near- $D_3$  symmetry,<sup>88</sup> a structure originally deduced from the fluorescence spectrum of the europium complex and subsequently confirmed by X-ray diffraction (Figure 19).

Complexes of 4-alkylated terpyridyls,  $[\text{Ln}(\text{4-Rterpy})_3](\text{ClO}_4)_3$  ( $\text{Ln} = \text{La}, \text{Eu}, \text{Tb}$ ;  $\text{R} = \text{Et}, \text{Bu}^t$ ) have much higher luminescence efficiency, possibly due to the bulk of the alkyl group preventing approach of deactivating molecules, as well as their electronic effects.

The chemistry of lanthanide nitrate complexes of terpy is complicated;<sup>89,90</sup> various formulae occur, depending not

**Figure 19** The structure of  $\text{Eu(terpy)}_3^{3+}$

least upon the solvent used. Reaction of a 1:1 molar ratio of the hydrated lanthanide nitrate with terpy in MeCN, the initial products are  $[\text{Ln(terpy)(NO}_3)_3(\text{H}_2\text{O})_x]$ . For the later lanthanides,  $\text{Ln(terpy)(NO}_3)_3(\text{H}_2\text{O})\cdot\text{terpy}$  ( $\text{Ln} = \text{Ho, Er, Tm, Yb}$ ) can be obtained when an excess of terpy is used. Simple 1:1 complexes  $\text{Ln(terpy)(NO}_3)_3(\text{H}_2\text{O})$  ( $\text{Ln} = \text{Nd, Eu, Tb}$ ) and  $\text{Ln(terpy)(NO}_3)_3$  ( $\text{Ln} = \text{Yb, Lu}$ ) have been described. All these complexes feature solely bidentate nitrates. In  $[\text{Lu(terpy)(NO}_3)_3]$ , the Lu–N distances are 2.379–2.407 Å and Lu–O bonds fall into the range 2.350–2.440 Å, so that even with the smallest lanthanide ion, all the nitrates are symmetrically bidentate. In contrast to the early lanthanides, where the same complex is obtained from synthesis in either acetonitrile or ethanol, the choice of solvent affects the structure for the 1:1 complexes of later lanthanides, with  $[\text{Ln(terpy)(NO}_3)_3\cdot(\text{C}_2\text{H}_5\text{OH})]$  ( $\text{Ln} = \text{Y, Ho–Lu}$ ) being obtained from ethanol. These contain two bidentate nitrates and one monodentate nitrate as well as a coordinated ethanol, the lanthanide being nine-coordinate. Replacement of a bidentate nitrate trans- to the terpy by a coordinated ethanol and a monodentate nitrate causes a little reorganization in the coordination sphere; the Lu–O(ONO<sub>2</sub>) distance is 2.279 (3) Å, showing that the Lu–O bond is about 0.1 Å shorter than for an oxygen atom in a bidentate nitrate group. A second oxygen in this monodentate nitrate is hydrogen-bonded to the coordinated ethanol molecule (Lu–O = 2.297 (3) Å). Another feature of these compounds is short C–H···O interactions involving nitrate oxygens and hydrogens of the terpyridyl ligand in other molecules. Use of methanol as the reaction solvent results in a different product for La and Ce only, 11-coordinate  $[\text{La(NO}_3)_3(\text{terpy})(\text{MeOH})_2]$  ( $\text{Ln} = \text{La, Ce}$ ). If the hydrated lanthanide nitrates are reacted with 1 mol of terpy in MeCN, followed by recrystallisation of the initial complex from water, different complexes are obtained, 10-coordinate  $[\text{Ln(terpy)(NO}_3)_2(\text{H}_2\text{O})_3] \text{NO}_3$  ( $\text{Ln} = \text{La–Gd}$ )

and nine-coordinate  $[\text{Ln(terpy)(NO}_3)_2(\text{H}_2\text{O})_2] \text{NO}_3\cdot 2\text{H}_2\text{O}$  ( $\text{Ln} = \text{Tb, Lu, Y}$ ). They result from solvolysis by water of a nitrate group in  $[\text{Ln(terpy)(NO}_3)_3(\text{H}_2\text{O})_x]$ . Structures show a girdle of ligands comprising a virtually planar terdentate terpy ligand and two or three water molecules coordinated round the lanthanide, with bidentate nitrates completing the coordination sphere above and below the metal ion.

Most lanthanide nitrate complexes have a 1:1 metal:terpy ratio. However, the complex  $\text{Ln(terpy)}_{1.5}(\text{NO}_3)_3$  was isolated from a MeCN solution with a 8:1 terpy:La ratio and was found to be  $[\text{Ln(terpy)}_2(\text{NO}_3)_2]^+ [\text{Ln(terpy)(NO}_3)_4]^-$ . Reaction of hydrated lanthanide nitrates with up to 4 mols of terpy in  $\text{CH}_3\text{CN}$  afford complexes with a similar 1.5:1 stoichiometry,  $[\text{Ln(terpy)}_2(\text{NO}_3)_2]^+ [\text{Ln(terpy)(NO}_3)_4]^-$  ( $\text{Ln} = \text{Nd, Sm, Tb, Dy, Ho}$ ). In these, the lanthanide is 10-coordinate in both the cation and the anion, one nitrate group in the anion being monodentate, in contrast to the anion in the 1.5:1 complex of the larger lanthanum ion, where all nitrates are bidentate, this is evidently a consequence of congestion arising around the smaller lanthanide ions. Ce is also 11-coordinate in  $(\text{Hpy})[\text{Ce(NO}_3)_4(\text{terpy})]\cdot\text{py}$ . The  $[\text{Sm(terpy)(NO}_3)_4]^-$  anion has also been isolated as the  $(\text{terpyH}_2)^{2+}$  salt, this has an 11-coordinate anion with four bidentate nitrates, in contrast to the three bidentate and one monodentate group in the  $[\text{Sm(terpy)}_2(\text{NO}_3)_2]^+$  salt, so solid-state packing effects seem important in determining coordination geometry.

A few lanthanide carboxylate complexes of terpy have been made, such as mononuclear  $[\text{Yb(O}_2\text{CCCl}_3)_3\cdot(\text{terpy})\cdot\text{MeOH}]$  in which coordinated methanol and two unidentate carboxylates and one bidentate carboxylate afford eight-coordinate ytterbium; in dimeric  $[\text{Ln(O}_2\text{CCCl}_3)_3\cdot(\text{terpy})\cdot(\text{H}_2\text{O})_2]$  ( $\text{Ln} = \text{La–Nd}$ ) the lanthanides are nine-coordinate. Some mixed-ligand quaternary complexes involving terpy,  $[\text{Ln(terpy)(NO}_3)_2(\text{acac})(\text{H}_2\text{O})_n]$  ( $\text{Ln} = \text{La, Pr, } n = 1; \text{Ln} = \text{Nd–Lu, } n = 0$ ), exhibit three different solid-state structures.  $[\text{La(terpy)(NO}_3)_2(\text{acac})(\text{H}_2\text{O})]$  is 10-coordinate, with two bidentate nitrates and a chelating diketonate and a coordinated water;  $[\text{Pr(terpy)(NO}_3)_2(\text{acac})(\text{H}_2\text{O})]$  is nine-coordinate, with one monodentate and one bidentate nitrate and a chelating diketonate and a coordinated water; and the remainder are  $[\text{Ln(terpy)(NO}_3)_2(\text{acac})]$  ( $\text{Nd–Lu}$ ) with two bidentate nitrates and a chelating diketonate.

Structures are known of three types of complex of  $\text{tptz}\cdot[\text{Sm(tptz)(NO}_3)_3(\text{H}_2\text{O})]\cdot 2\text{H}_2\text{O}$  has 10-coordinate Sm with all nitrates bidentate;  $[\text{Eu(tptz)Cl}_3(\text{MeOH})_2]\cdot 2\text{MeOH}$  features eight-coordinate europium, and in dimeric  $[\text{Pr(tptz)(OAc)}_3]_2\cdot 2\text{MeOH}$  praseodymium achieves 10-coordination through forming double  $(\eta^2, \mu-1, 1)$  acetate bridges familiar in other lanthanide carboxylate complexes. A study<sup>91</sup> of complexes of 4-amino-bis(2,6-(2-pyridyl))-1,3,5-triazine (abtptz) with all the lanthanide nitrates gives a good deal of insight into how the stoichiometry and structure of complexes depend upon factors such as the radius

of the metal ion, the composition of the reaction mixture and the solvent employed. Complexes whose structures are known are  $[\text{La}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})_2]$  (11-coordinate),  $[\text{Ln}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})]$  ( $\text{Ln} = \text{La}, \text{Pr}–\text{Sm}$ ; 10-coordinate),  $[\text{Ln}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})]$  ( $\text{Ln} = \text{Yb}, \text{Y}$ ; nine-coordinate, with one monodentate nitrate),  $[\text{Ln}(\text{abptz})(\text{NO}_3)_2(\text{H}_2\text{O})_3]\text{NO}_3$  ( $\text{Ln} = \text{Nd}, \text{Sm}$ ; 10-coordinate) and  $[\text{Ln}(\text{abptz})(\text{NO}_3)_2(\text{H}_2\text{O})_2]\text{NO}_3$  ( $\text{Ln} = \text{Eu}–\text{Lu}$ ; nine-coordinate). Unlike the succeeding metals, La forms 10 and 11-coordinate  $[\text{La}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})_n]$  ( $n = 1, 2$ ), showing that the position of lanthanum as the largest lanthanide ion sometimes causes it to behave atypically; these complexes have similar solubilities and crystallize from the same reaction mixture. If the structures of these two complexes are compared, it can be seen that the decrease in coordination number from 11 to 10 is accompanied by a decrease in La–O (water) distance from 2.589 (4) and 2.610 (4) Å to 2.483 (5) Å; similarly, the La–N distances decrease from 2.739 (4), 2.755 (5) and 2.805 (6) in the 11-coordinate compound to 2.576 (5), 2.625 (5) and 2.641 (5) Å in 10-coordinate  $[\text{La}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})]$ . The range of La–O (nitrate) distances decreases from 2.628 (4)–2.702 (5) Å (with an outlying member at 2.805 (6) Å) in  $[\text{La}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})_2]$ , to 2.525 (5)–2.620 (5) Å in  $[\text{La}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})]$ , indication of the congestion in the coordination sphere in the 11-coordinate complex. It indicates how nitrate is a versatile ligand in enabling lanthanide ions to achieve high coordination numbers.  $[\text{Ln}(\text{abptz})(\text{NO}_3)_2(\text{H}_2\text{O})_3]\text{NO}_3$  ( $\text{Ln} = \text{Nd}, \text{Sm}$ ; 10-coordinate) and  $[\text{Ln}(\text{abptz})(\text{NO}_3)_2(\text{H}_2\text{O})_2]\text{NO}_3$  ( $\text{Ln} = \text{Eu}–\text{Lu}$ ) are clearly analogous to terpy complexes mentioned above. On the other hand, the fact that abptz forms nine-coordinate  $[\text{Ln}(\text{abptz})(\text{NO}_3)_3(\text{H}_2\text{O})]$  ( $\text{Ln} = \text{Yb}, \text{Y}$ ) are, with one monodentate nitrate, rather than the alternative  $[\text{Ln}(\text{abptz})(\text{NO}_3)_3]$ , with three bidentate nitrates, analogous to  $[\text{Ln}(\text{terpy})(\text{NO}_3)_3]$  ( $\text{Ln} = \text{Er}–\text{Lu}$ ) indicates the subtle factors that can be responsible for the adoption of a particular geometry in a lanthanide complex.

Other ligands of the type whose complexation has been examined in detail include a range of 2,6-bis(5,6-dialkyl-1,2,4-triazin-3-yl)pyridines, 2,6-bis(benzimidazol-2'-yl)pyridine (bzimpy) and  $N,N,N',N'$ -tetraethylpyridine-2,6-dicarboxamide. In some cases, segmental ligands have been employed to obtain complexes with stranded helical structures.

Among tetradentate ligands, complexes of the tripodal tpza and tpa have been explored.  $[\text{Ln}(\text{tpa})\text{Cl}_3]$  ( $\text{Ln} = \text{Eu}, \text{Tb}, \text{Lu}$ ) have seven-coordination, whilst the larger neodymium ion can accommodate a coordinated solvent molecule in the eight-coordinate Nd analogue,  $[\text{Nd}(\text{tpa})\text{Cl}_3(\text{MeOH})]$ . Eight-coordinate lanthanum iodide complexes  $[\text{La}(\text{tpza})\text{I}_3(\text{NCMe})]$  and  $[\text{La}(\text{tpza})\text{I}_3(\text{thf})]$  exist. When lanthanide ions complex with the tripodal ligand tris(2-benzimidazol-2-ylmethyl)amine (ntb), bis complexes  $[\text{Ln}(\text{ntb})_2]^{3+}$  are formed where the ligand encapsulates the metal – to the exclusion of chloride from the coordination sphere, even when a deficit of

ligand is used. Strong  $\pi-\pi$  interactions between the benzimidazole rings may be responsible. However, 1:1 complexes  $[\text{Ln}(\text{ntb})(\text{NO}_3)_3]\cdot\text{H}_2\text{O}$  ( $\text{Ln} = \text{La}, \text{Ce}, \text{Nd}, \text{Sm}–\text{Dy}, \text{Er}$ ) are formed when nitrate, with its stronger coordinating tendencies, is present. A chiral tris(2-pyridylmethyl)amine ligand has been used to form complexes  $[\text{Ln}(\text{L})](\text{CF}_3\text{SO}_3)_3$  ( $\text{Ln} = \text{Eu}$  and  $\text{Tb}$ ) whose emission spectra of the europium complex in particular are most sensitive in both intensity and in line shape to the presence of a wide range of anions ( $\text{X} = \text{I}^-$ ,  $\text{Br}^-$ ,  $\text{Cl}^-$ ,  $\text{F}^-$ ,  $\text{ClO}_4^-$ ,  $\text{NO}_3^-$ ,  $\text{SCN}^-$ ,  $\text{CH}_3\text{CO}_2^-$ ,  $\text{HSO}_4^-$  and  $\text{H}_2\text{PO}_4^-$ ), working most effectively as a nitrate-specific luminescent sensor.<sup>92</sup>

The tetradentate quaterpyridine and hexadentate sexipyridine ligands form 1:1 complexes with yttrium and europium nitrates, respectively; the first-named ligand generates nine-coordinate  $[\text{Y}(\text{qtpy})(\text{NO}_3)_2(\text{H}_2\text{O})]^+$  cations while the latter produces 10-coordinate  $[\text{Eu}(\text{spy})(\text{NO}_3)_2]^+$  cations where the ligand twists itself helically round the metal.<sup>93</sup>

### 3.7.11 Complexes of Porphyrins, Phthalocyanines, Aza Macrocycles, Texaphyrins, and Related Ligands

Reaction of  $\text{Ln}(\text{acac})_3$  with  $\text{H}_2\text{TPP}$  and other porphyrins (*see Porphyrin*) in solvents like trichlorobenzene (TCB) have been reported to give complexes  $\text{Ln}(\text{acac})(\text{porph})$ , although for the early lanthanides  $\text{LnH}(\text{porph})_2$  seems to be the more usual product (on extended reflux, the double-decker sandwich  $\text{Ln}_2(\text{porph})_3$  may be obtained). Thus, refluxing  $[\text{Eu}(\text{acac})_3]$  with  $\text{H}_2\text{OEP}$  in 1,2,4-trichlorobenzene for 4 h leads to a mixture of  $[\text{Eu}(\text{OEP})_2]$  and  $[\text{Eu}_2(\text{OEP})_3]$  (along with a small amount of  $[\text{Eu}(\text{OEP})(\text{OAc})]$ ), the former being a good deal more soluble in organic solvents, so that the mixture is separable by crystallisation.<sup>94</sup> Other, less forcing, methods have been described, such as when  $[\text{LuR}_3]$  ( $\text{R} = \text{CH}(\text{SiMe}_3)_2$ ) reacts with  $\text{H}_2\text{OEP}$  in toluene forming  $[\text{Ln}(\text{OEP})\text{CH}(\text{SiMe}_3)_2]$ , which has a square-pyramidal structure with a highly dished porphyrin skeleton.<sup>95</sup> Among adducts of porphyrins, a rare example of seven-coordination is found in  $[\text{Ln}(\text{TPP})\text{Cl}(\text{dme})]$  ( $\text{Ln} = \text{Ho}, \text{Er}, \text{Tm}, \text{Yb}$ ) where the metal sits about 1.1 Å above the  $\text{N}_4$  plane.<sup>96</sup> Bis(porphyrin) complexes with sandwich structures have also been synthesized. In general they are formally regarded as complexes of the trivalent lanthanide where one of the porphyrin ligands is a dianion and the other the oxidized cation radical. Genuine cerium(IV) complexes of both porphyrins and phthalocyanines have, however, been made. Phthalocyanine complexes can be made by heating a lanthanide compound such as the acetate with 1,2-dicyanobenzene.

A number of other complexes involve the lanthanide bonding to nitrogens in rings, either in aza crowns or in more classic macrocycles like cyclen. 1,4,7,10,13-pentaazacyclopentadecane (L) forms nitrate complexes  $[\text{Ln}(\text{L})(\text{NO}_3)_3]$  ( $\text{Ln} = \text{Y}, \text{La}–\text{Yb}$  except  $\text{Ce}, \text{Pm}, \text{Ho}$ ); the structure of  $[\text{La}(\text{L})(\text{NO}_3)_3]$  shows it to have 11-coordinate lanthanum. As another example of structurally characterised

complex of a N-donor macrocycle,  $[\text{Nd}([18]\text{aneN}_6)(\text{NO}_3)_3]$  has two monodentate and one bidentate nitrate giving 10-coordination.

Cryptate complexes with macrobicyclic ligands containing three bipy units, in which the  $\text{Ln}^{3+}$  ion is contained within a ligand cavity, have been synthesized.<sup>97</sup> Such ligands will complex  $\text{Ln}^{2+}$  ions, such as  $\text{Eu}^{2+}$  and  $\text{Sm}^{2+}$ , under conditions where  $\text{Ln}^{3+}$  ions are not. An application has been using lanthanide cryptates of the early lanthanides (La, Ce, Eu) as catalysts in the hydrolysis of phosphate monoesters, diesters, and triesters. Schiff base complexes can be synthesized by the reaction of a lanthanide salt with a diamine and a suitable carbonyl derivative such as 2,6-diacetylpyridine.

Complexes, particularly of gadolinium, of ligands with a  $\text{N}_4$ -donor macrocyclic backbone that also supports carboxylate groups have assumed importance in the context of MRI contrast agents (see Section Magnetic Resonance Imaging and MRI Agents and *see also Metal-based Imaging Agents*). The potentially octadentate ligand DOTA (1,4,7,10-tetra(carboxymethyl)-1,4,7,10-tetraazacyclododecane) has been widely studied. It forms very stable lanthanide complexes (one water usually molecule coordinated)  $[\text{Ln}(\text{DOTA})(\text{H}_2\text{O})]^-$ . These have slightly higher stability constants than the DTPA complexes; thus  $\log K$  for  $[\text{Gd}(\text{DOTA})(\text{H}_2\text{O})]^-$  is  $\sim 24.7$ , in comparison with 22.46 for  $[\text{Gd}(\text{DTPA})(\text{H}_2\text{O})]^{2-}$ .  $[\text{Gd}(\text{DOTA})(\text{H}_2\text{O})]^-$ , (Figure 20) is in clinical use (gadoterate meglumine; Dotarem<sup>TM</sup>).<sup>98</sup> The structures of several lanthanide complexes of DOTA have been examined.  $\text{Na}[\text{Ln}(\text{DOTA})(\text{H}_2\text{O})] \cdot 4\text{H}_2\text{O}$  all contain nine-coordinate  $[\text{Ln}(\text{DOTA})(\text{H}_2\text{O})]^-$  ions ( $\text{Ln} = \text{Pr}, \text{Nd}, \text{Eu}, \text{Gd}, \text{Ho}, \text{Lu}$ ) with twisted square-antiprismatic arrangements of the antiprism (on which the coordinated water molecule is superimposed), whilst  $\text{K}[\text{Tm}(\text{DOTA})] \cdot 6\text{H}_2\text{O}$  contains no coordinated water, showing the role of the counterion in determining the species crystallizing.

If one carboxylic acid side chain in  $\text{H}_4\text{DOTA}$  is replaced by hydrogen, the resulting acid,  $\text{H}_3\text{DO3A}$ , forms neutral lanthanide complexes. In solution, they are believed to have two water molecules coordinated so that the

Figure 20 The MRI agent  $[\text{Gd}(\text{DOTA})(\text{H}_2\text{O})]^-$

species present is  $\text{Gd}(\text{DO3A})(\text{H}_2\text{O})_2 \cdot [\text{Eu}(\text{DO3A})(\text{H}_2\text{O})_n]$  is known to exhibit a hydration equilibrium with  $n = 1, 2$ , strongly weighed towards  $[\text{Eu}(\text{DO3A})(\text{H}_2\text{O})_2]$ . Other derivatives have been made in which the fourth carboxylic acid group is replaced by hydroxyalkyl groups that are marketed and approved for use ( $-\text{CH}_2\text{CH}(\text{CH}_3)\text{OH} = \text{ProHance}^{\text{TM}}$ ;  $-\text{CH}(\text{CH}_2\text{OH})\text{CH}(\text{OH})\text{CH}_2\text{OH} = \text{Gadovist}^{\text{TM}}$ ). These compounds have a side-chain hydroxyalkyl group coordinated, in addition to four nitrogens, three carboxylate oxygens, and a water molecule (Figure 21).

Quite apart from use as MRI contrast agents, there is considerable interest in applications of lanthanide complexes of DOTA and related complexing agents as spectroscopic probes.<sup>99</sup>

Examples of this include some Tb and Eu macrocyclic complexes, immobilised in a sol-gel glass, whose emission is made pH-dependent and can thus be used as narrow range pH sensors, and a terbium complex which behaves as a molecular logic gate; the output (a terbium emission line) is only observed when the 'inputs' (the presence of proteins and the absence of oxygen) are both satisfied. (Figure 22).

*Texaphyrins.* A new type of complex is provided by the texaphyrins, compounds of 'extended' porphyrins where

Figure 21 The neutral complex  $[\text{Gd}(\text{DO3A})(\text{H}_2\text{O})_2]$

Figure 22 A terbium complex that acts as a 'logic gate'

**Figure 23** The gadolinium texaphyrin complex 'Gd-tex'

the ring contains five donor nitrogens. These have attracted considerable interest because of their possible medicinal applications.<sup>100</sup> Two texaphyrin complexes are undergoing clinical trials; a gadolinium compound (Gd-tex; XCYTRIN<sup>TM</sup>) is an effective radiation sensitiser for tumour cells (Figure 23). It assists the production of reactive oxygen-containing species, whilst the presence of the Gd<sup>3+</sup> ion means that the cancerous lesions to which it localises can be studied by MRI. One form of the lutetium analogue (LUTRIN<sup>TM</sup>), is being developed for photodynamic therapy for breast cancer, and another, (ANTRIN<sup>TM</sup>) is being developed for photoangioplasty, where it has potential for treating arteriosclerosis.

### 3.7.12 Other Ligands

**Alkoxides and Aryloxides**<sup>101</sup>. Some of these compounds have been known for over 30 years, but interest in the former has been stimulated recently by their potential use as precursors for deposition of metal oxides using the sol-gel (see *Sol-Gel Synthesis of Solids*) or Metal Organic Chemical Vapour Deposition (MOCVD) process (see *Metal-Organic Chemical Vapor Deposition*). In the case of alkoxides and aryloxides, it is harder to get monomers with low coordination numbers than with alkyl (and aryl-) amides, since -OR ligands by their own nature exert less second-order influence in the coordination sphere than the corresponding -NR<sub>2</sub>, and, for the same reason, -OR groups are much more likely to be found in bridging positions. Thus, because of oligomerization and/or the presence of solvent in the coordination sphere, Ln(OR)<sub>3</sub> species are frequently not three-coordinate.

Simple methoxides like La(OMe)<sub>3</sub> are ill-defined structurally but are oligomeric; attempted isolation of corresponding isopropoxides has yielded the clusters Ln<sub>5</sub>O(O-*i*-Pr)<sub>13</sub> (Figure 24) (Ln = Y, Yb) with a square-pyramidal core, Nd<sub>5</sub>O(O-*i*-Pr)<sub>13</sub>(*i*-PrOH)<sub>2</sub> (trigonal bipyramidal core),

**Figure 24** The structure of Y<sub>5</sub>O(O-*i*-Pr)<sub>13</sub>

and Nd<sub>6</sub>(O-*i*-Pr)<sub>17</sub>Cl. Under other circumstances, a binuclear solvate, [Nd(OCHPr<sup>*i*</sup>)<sub>3</sub>(thf)]<sub>2</sub>, with the structure [(Pr<sup>*i*</sup>CHO)<sub>2</sub>(thf)Nd(μ-OCHPr<sup>*i*</sup>)<sub>2</sub>Nd(thf)(OCHPr<sup>*i*</sup>)<sub>2</sub>] has been obtained. Similarly, the neopentoxides Ln(OCH<sub>2</sub>Bu<sup>*t*</sup>)<sub>3</sub> (Ln = La, Nd) are tetrameric [Ln(OCH<sub>2</sub>Bu<sup>*t*</sup>)<sub>3</sub>]<sub>4</sub> based on a square of lanthanides with each lanthanide bound to one terminal and four bridging alkoxides. Using the bulkier *t*-butoxide ligand to minimize association gave La<sub>3</sub>(O-*t*-Bu)<sub>9</sub>(thf)<sub>2</sub> and Ce(O-*t*-Bu)<sub>3</sub> (believed to be monomeric); the latter undergoes thermolysis in high yield:

The product is an alkoxy-bridged dimer with four-coordinate cerium. Dimeric structures are also exhibited by [Ln(OQPh)<sub>3</sub>]<sub>2</sub> (Ln = La, Ce, Y; Q = C, Si), although the bridges are cleaved by Lewis bases forming adducts such as Ln(OSiPh)<sub>3</sub>(thf)<sub>3</sub> (*fac*-octahedral; Ln = Y, La, Ce) and Y(OSiPh)<sub>3</sub>(OPBu<sub>3</sub>)<sub>2</sub> (trigonal bipyramidal). An unusual cyclic decameric structure is exhibited by [Y(OC<sub>2</sub>H<sub>4</sub>OMe)<sub>3</sub>]<sub>10</sub> (Figure 25).

Synthesis of alkoxides from LnCl<sub>3</sub> is often complicated by chloride retention from the starting material, and for this reason they are often made by alcoholysis of Ln(N(SiMe<sub>3</sub>)<sub>2</sub>)<sub>3</sub>.

A range of aryloxides exists. With 2,6-dimethylphenoxide, six-coordinate Y(OR)<sub>3</sub>(thf)<sub>3</sub> (and dimeric [Y(OR)<sub>3</sub>(thf)]<sub>2</sub> with five-coordinate) are formed; replacement of methyl by phenyl substituents leads to the isolation of the 2,6-diphenylphenolates [Ln(OC<sub>6</sub>H<sub>3</sub>Ph<sub>2</sub>-2,6)<sub>3</sub>] (Ln = La, Ce, Pr, Nd, Gd, Ho, Er, Lu, Y), which have monomeric structures with the lanthanide slightly out of the O<sub>3</sub> plane, but with some additional ring-metal interactions. [Ln(OC<sub>6</sub>H<sub>3</sub>Ph<sub>2</sub>-2,6)<sub>3</sub>(thf)<sub>2</sub>].2thf (Ln = La, Nd) have conventional five-coordinate trigonal bipyramidal coordination of the metal with one axial and one equatorial thf; in contrast, [Nd(OC<sub>6</sub>H<sub>3</sub>Ph<sub>2</sub>-2,6)<sub>3</sub>(thf)] has pseudo-tbp coordination with three equatorial

Figure 25 Cyclic decameric structure of  $[Y(OC_2H_4OMe)_3]_{10}$

phenoxides, an apical thf and an apical position occupied by a phenyl group. Using the 2,6-diisopropylphenolate ligand leads to unsolvated  $Ln(OC_6H_3Pr_2-2,6)_3$  species which are in fact  $\eta^6$ -arene bridged dimers  $Ln_2(OC_6H_3Pr_2-2,6)_6$ ; in thf, they form conventional trigonal bipyramidal thf adducts  $[Ln(OC_6H_3Pr_2-2,6)_3(thf)_2]$  ( $Ln = Pr, Nd, Sm, Gd, Er, Yb, Lu$ ). When the bulk of the aryloxide is increased by putting two *t*-butyl groups into the 2,6-positions of the benzene ring, three-coordinate aryloxides,  $Ln(O-2,6-*t*-Bu_2-4-R-C_6H_2)_3$ , can be isolated ( $R = H, Ln = Y, La, Sm; R = Me, Ln = Y, La, Ce, Pr, Nd, Dy-Er, Yb$ ). Trigonal planar geometry is found in  $Y(O-*t*-Bu_2C_6H_3)_3$  but a pyramidal structure is adopted in  $Ce(O-2,6-*t*-Bu_2-4-Me-C_6H_2)_3$ . Possibly the balance of small and variable 'agostic' and Van der Waals forces, whether within the lattice or within the complex species, is the determining factor in determining the form of three-coordination. Alkyl and aryloxides have proved useful synthetic precursors.

**Alkylamides.** The volatile air-sensitive silylamides are the best characterized alkylamides. They are made by salt-elimination reactions:

They are volatile in vacuo at 100°C and dissolve in hydrocarbons; the first three-coordinate lanthanide compounds to be characterized, they have unusual pyramidal structures (Figure 26) in the solid state (similar structures have been reported for Y, Ce, Nd, Sm, Eu, Dy,

Figure 26 Three-coordinate  $Ln[N(SiMe_3)_2]_3$

Er, and Yb), but are believed to be planar in solution. Careful examination of the crystal structure of  $[Sm\{N(SiMe_3)_2\}_3]$  shows that one methyl group in each amide is placed above the pyramid relatively close to the samarium ( $Sm-C$  3.003(4) Å; compare  $Sm-N$  2.284(3) Å) suggesting the presence of agostic interactions (see *Agostic Bonding*). DFT (Density Field Theory) calculations on it support this view, indicating the presence of  $\beta$ -Si-C agostic interactions.<sup>102</sup>  $Ln(N(SiMe_3)_2)_3$  form stable four-coordinate  $Ph_3PO$  and  $Ph_2CO$  adducts; when excess phosphine oxide is used, five-coordinate peroxide-bridged dimers are obtained.  $Eu[N(SiMe_3)_2]_3$  forms both 1:1 and 1:2 adducts with  $Me_3PO$ .  $[Ln(N(SiMe_3)_2)_3]$  react with  $CyNC$  ( $Cy =$  cyclohexyl) forming trigonal bipyramidal five-coordinate adducts  $[Ln(N(SiMe_3)_2)_3(CyNC)_2]$  (axial nitriles).  $[Y(N(SiMe_3)_2)_3(PhCN)_2]$  has a similar structure.

When a deficit of the lithium alkylamide is used, dimeric chloride-bridged silylamides are obtained which are useful synthetic intermediates (Figure 27);<sup>103</sup> they can also be prepared by redistribution reactions between  $LnCl_3$  and  $[Ln(N(SiMe_3)_2)_3]$ ; some bromo- and iodo- analogues have been reported.

Anhydrous lanthanide triflates are an alternative to the chlorides as starting materials for the synthesis of  $[Ln(N(SiMe_3)_2)_3]$  as they obviate problems of chloride retention in the product, which can lead to several products, as reaction of  $YbCl_3$  and  $NaN(SiMe_3)_2$  in a 1:2 molar ratio gives  $[Yb(N(SiMe_3)_2)_3]$ ,  $[Yb(N(SiMe_3)_2)_2(\mu-Cl)(thf)]_2$  and  $[Yb_3Cl_4O((N(SiMe_3)_2)_3(thf)_3)]$ . The latter is a trinuclear cluster with a triangle of ytterbiums, where Yb is octahedrally coordinated by an amide nitrogen, a thf, two  $\mu_2$ -chlorine atoms and a  $\mu_3$ -chlorine and  $\mu_3$ -oxygen.

The amide  $Er\{NBu^t(SiMe_2H)\}_3$ , which has an unexpectedly high vapour pressure, displays three agostic  $Er-H-Si$  interactions in the solid state. Other alkylamides  $Ln(N-*i*-Pr)_3$  ( $Ln = Y, La, Nd, Yb, Lu$ ), are obtained with the less hindered isopropylamide ligand; the neodymium compound forms

**Figure 27** Reactions of lanthanide bis(trimethylsilyl)amide complexes. (Ref. 6. Reproduced by permission of Palgrave Macmillan)

a stable thf adduct  $[\text{Nd}(\text{N-}i\text{-Pr}_2)_3(\text{thf})]$ .  $[\text{Sm}(\text{Ncy}_2)_3(\text{thf})]$  is similar. In contrast to the three-coordinate silylamides and diisopropylamides, the lanthanides do not form simple homoleptic dimethylamides. Reaction of  $\text{NdCl}_3$  with  $\text{LiNMe}_2$  gives an adduct  $[\text{Nd}(\text{NMe}_2)_3(\text{LiCl})_3]$ , which with  $\text{MMe}_3$  ( $\text{M} = \text{Al}, \text{Ga}$ ) gives bridged  $[\text{Nd}(\text{NMe}_2)_3(\text{MMe}_3)_3]$ .

Trigonal bipyramidal  $[\text{Ln}\{\text{N}(\text{SiHMe}_2)_2\}_3(\text{thf})_2]$  ( $\text{Ln} = \text{Y}, \text{La-Lu}$ ) are isostructural; these amides have been anchored to the internal walls of the mesoporous silicate MCM-41 as potential catalyst precursors.

Rather less is known about lanthanide arylamides. Reaction of  $\text{NdCl}_3$  with  $\text{KNHAr}$  ( $\text{Ar} = \text{Ph}$ ) leads to  $[\text{Nd}(\text{NHPh})_3 \cdot 3\text{KCl}]$ , reminiscent of the adducts of the dimethylamides. Using the sterically demanding 2,6- $\text{Pr}_2\text{C}_6\text{H}_3$  group leads to octahedral  $[\text{Nd}(\text{NH-2,6-Pr}_2\text{C}_6\text{H}_3)_3(\text{thf})_3]$  and trigonal bipyramidal  $[\text{Ln}(\text{NH-2,6-Pr}_2\text{C}_6\text{H}_3)_3(\text{thf})_2]$  ( $\text{Ln} = \text{Y}, \text{Yb}$ ).

Several compounds with highly fluorinated amides have been synthesized;  $[\text{Sm}(\text{N}(\text{SiMe}_3)(\text{C}_6\text{F}_5))_3]$  (Figure 28) contains three significant  $\text{Sm} \cdots \text{F}$  and three  $\text{Sm}-\text{C}-\text{H}$  agostic interactions, which seem to be common in these compounds; the thf adduct  $[\text{Sm}(\text{N}(\text{C}_6\text{F}_5)(\text{SiMe}_3))_3(\text{thf})]$  has two  $\text{Sm} \cdots \text{F}$  and one  $\text{Sm}-\text{C}$  agostic interaction. The toluene adduct  $[(\eta^6\text{-C}_6\text{H}_5\text{Me})\text{Nd}(\text{N}(\text{C}_6\text{F}_5)_2)_3]$  has a  $\eta^6$ -bonded toluene molecule with a distorted piano-stool geometry. Tetrahedral anionic species  $[\text{Li}(\text{thf})\text{Ln}(\text{N-}i\text{-Pr}_2)_4]$  ( $\text{Ln} = \text{La}, \text{Y}, \text{Lu}$ ) and  $[\text{Li}(\text{thf})_4][\text{Ln}(\text{NPh}_2)_4]$  ( $\text{Ln} = \text{Er}, \text{Yb}$ ) have also been made.

**Figure 28** The samarium amide  $[\text{Sm}(\text{N}(\text{SiMe}_3)(\text{C}_6\text{F}_5))_3]$ , showing the agostic interactions

*Polypyrazolylborates.* This area of chemistry has developed considerably.<sup>104</sup>  $[\text{LnTp}_3]$  have nine-coordinate structures for early lanthanides (e.g. Pr, Nd), but eight-coordinate for the later metals (e.g. Yb). Seven-coordinate bis complexes  $[\text{Ln}(\text{Tp})_2\text{Cl}]$  are formed using totally moisture-free conditions, but these readily add a Lewis base, for example, water forming  $[\text{Ln}(\text{Tp})_2\text{Cl}(\text{H}_2\text{O})]$ . A very wide range of compounds, many of Sm, Eu, and Yb, in both the +2 and +3 states, has been synthesized with  $\text{Tp}^{\text{Me}_2}$ , this time with a maximum of two  $\text{Tp}^{\text{Me}_2}$  bound. In triflate complexes

$\text{Ln}(\text{Tp}^{\text{Me}_2})_2(\text{OTf})$ , triflate coordinates for the lighter lanthanides, as in  $[\text{Nd}(\text{Tp}^{\text{Me}_2})_2(\text{O}_3\text{SCF}_3)]$  whereas the smaller lanthanides form ionic  $[\text{Ln}(\text{Tp}^{\text{Me}_2})_2] \text{O}_3\text{SCF}_3$ , as in the ytterbium compound. The triflates form mono(MeCN) adducts, the MeCN being bound in  $[\text{La}(\text{Tp}^{\text{Me}_2})_2(\text{MeCN})] \text{O}_3\text{SCF}_3$  but not in  $[\text{Nd}(\text{Tp}^{\text{Me}_2})_2(\text{O}_3\text{SCF}_3)] \cdot \text{MeCN}$ . This can be regarded as a type of ionisation isomerism. In a range of  $\text{Sm}(\text{Tp}^{\text{Me}_2})_2\text{X}$  compounds, where  $\text{X} = \text{F}, \text{Cl}$ , these have monomeric seven-coordinate molecular structures, but for  $\text{X} = \text{I}$  and  $\text{BPh}_4$ , the compounds are  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2]^+\text{X}^-$ . A comparison of the ytterbium(II) and (III) compounds  $[\text{Yb}(\text{Tp}^{\text{Me}_2})_2]$  and  $[\text{Yb}(\text{Tp}^{\text{Me}_2})_2] \text{O}_3\text{SCF}_3$  show six-coordination for ytterbium in both cases, with Yb–N bond lengths ca. 0.16 Å longer in the Yb(II) compound.

**Simple Alkyls.** These are primarily dealt with elsewhere (see *Scandium, Yttrium & the Lanthanides: Organometallic Chemistry*) but the structural similarity of the distorted three-coordinate trigonal pyramidal structures of the alkyls  $[\text{Ln}((\text{CH}(\text{SiMe}_3)_2)_3)]$  to the alkylamides  $[\text{Ln}((\text{N}(\text{SiMe}_3)_2)_3)]$  ( $\text{Ln} = \text{La}–\text{Lu}$ ) is notable. Density Functional Theory calculations indicate that  $\beta$ -Si–C agostic interactions are important in these structures (see *Agostic Bonding*), but that the hitherto favoured  $\gamma$  C–H agostic interactions are in fact repulsive. Another family of alkyls with simple coordination geometries is  $[\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{thf})_n]$ . These appear to be very unstable for lanthanides larger than samarium, but  $[\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{thf})_3]$  ( $\text{Ln} = \text{Sm}, \text{Y}$ ) have *fac*-octahedral structures, whilst  $[\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{thf})_2]$  ( $\text{Ln} = \text{Er}, \text{Yb}, \text{Lu}$ ) all have five-coordinate trigonal bipyramidal structures (axial thf ligands). The  $[\text{Ln}(\text{CH}_3)_6]^{3-}$  ions (all lanthanides except Eu) have the expected octahedral structures.<sup>105</sup>

**Thiolates and Related Systems.** Lanthanide thiolates have only been characterized in detail recently. Monomeric species have been obtained using bulky ligands, such as the three-coordinate (pyramidal)  $\text{Sm}(\text{SC}_6\text{H}_2-t\text{-Bu-2,4,6})_3$  (Figure 29).<sup>106</sup>

The intensively reactive  $[\text{Ln}(\text{SBU}^t)_3]$  ( $\text{Ln} = \text{La}, \text{Ce}, \text{Pr}, \text{Nd}, \text{Eu}, \text{Yb}, \text{Y}$ ) are made<sup>107</sup> from  $[\text{Ln}\{\text{N}(\text{SiMe}_3)_2\}_3]$  and  $\text{HSBU}^t$ ; their reactivity is doubtless due to coordinative unsaturation. Some thiophenolates have been isolated as Lewis base adducts.  $[\text{Ln}(\text{SPh})_3(\text{py})_3]_2$  ( $\text{Ln} = \text{Ho}, \text{Tm}$ ) have two thiolate bridges with seven-coordinate lanthanides;  $[\text{Sm}(\text{SPh})_3(\text{py})_2]_4$  has a linear arrangement of four seven-coordinate samariums with 3, 2, and 3  $\mu_2$ -bridging thiolates and  $[\text{Sm}(\text{SPh})_3(\text{thf})]_{4n}$  is a polymer. Use of  $\text{SC}_6\text{F}_5$  as a ligand gives stabler (even to air) and more hydrocarbon-soluble products, also obtained as Lewis base adducts. The large  $\text{Ce}^{3+}$  ion forms the seven-coordinate dimer  $[\text{Ce}(\text{SC}_6\text{F}_5)_3(\text{thf})_3]_2$  with thiolate bridges, whilst Ho and Er give monomeric  $[\text{Ln}(\text{SC}_6\text{F}_5)_3(\text{thf})_3]$  ( $\text{Ln} = \text{Ho}, \text{Er}$ ). Other adducts  $[\text{Ln}(\text{SC}_6\text{F}_5)_3(\text{py})_4]$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) and  $[\text{Er}(\text{SC}_6\text{F}_5)_3(\text{dme})_2]$  have also been isolated. Many of these compounds feature  $\text{Ln} \cdots \text{F}$  interactions, of the type

**Figure 29** Structure of three-coordinate Sm in  $\text{Sm}(\text{SC}_6\text{H}_2(\text{Bu-}t)_3-2,4,6)_3$

noted in lanthanide amides. Another synthetic approach has utilized the reaction of lanthanide metals with disulphides and diselenides. Thus molecules such as  $[\text{Yb}(\text{SAr})_3(\text{py})_3]$  ( $\text{Ar} = 2,4,6$ -triisopropylphenyl) and  $\text{Ln}(\text{SePh})_3\text{py}_3$  ( $\text{Ln} = \text{Ho}, \text{Tm}, \text{Yb}$ ) have been made; the selenolates are dimeric with seven-coordinate lanthanides. In contrast,  $[\text{Yb}(\text{SPh})_3\text{py}_3]$  has a meridional, structure, whilst  $[\text{Ln}(\text{SePh})_3(\text{thf})_3]$  ( $\text{Ln} = \text{Tm}, \text{Ho}, \text{Er}$ ) have monomeric *fac*-octahedral structures.  $[\text{Sm}(\text{SePh})_3(\text{py})_3]_2$  has two selenothiolate bridges with seven-coordinate samarium. An important reaction of these compounds is that they react with free chalcogens forming clusters. Thf solutions of thiolates  $\text{Ln}(\text{SPh})_3$  reacts with S forming octanuclear clusters  $[\text{Ln}_8\text{S}_6(\text{SPh})_{12}(\text{thf})_8]$  ( $\text{Ln} = \text{Ce}–\text{Sm}, \text{Gd}–\text{Er}$ ), their structure is based on a cube of lanthanides, edge bridged by mercaptides and face-bridged by sulphur; analogous pyridine clusters  $[\text{Ln}_8\text{S}_6(\text{SPh})_{12}(\text{py})_8]$  ( $\text{Ln} = \text{Nd}, \text{Sm}, \text{Er}$ ) have also been isolated. Reaction of Sm with  $\text{PhSeSePh}$  in thf gives a cluster  $[\text{Sm}_8\text{Se}_6(\text{SePh})_{12}(\text{thf})_8]$  whilst  $\text{Sm}(\text{SePh})_3$  reacts with S in dme affording  $[\text{Sm}_7\text{S}_7(\text{SePh})_6(\text{dme})_7]^+ [\text{Hg}_3(\text{SePh})_7]^-$ .  $\text{Nd}(\text{SePh})_3$  reacts with Se in pyridine to form  $[\text{Nd}_8\text{Se}_6(\text{SePh})_{12}(\text{py})_8]$ . Reaction of later lanthanides with mixtures of  $\text{I}_2$  and  $\text{PhSeSePh}$  in thf, followed by reaction with Se in pyridine affords iodine-containing clusters  $[(\text{thf})_6\text{Ln}_4\text{I}_2(\text{SeSe})_4(\mu_4\text{-Se})] \cdot \text{thf}$  ( $\text{Ln} = \text{Ho}–\text{Yb}$ ). These contain a square array of Ln(III) ions connected through a single ( $\mu_4\text{-Se}$ ) ligand. Another such cluster is  $[\text{Yb}_6\text{Se}_6\text{I}_6(\text{thf})_{10}]$ . On thermolysis, these selenium rich compounds give iodine-free  $\text{Ln}_2\text{Se}_3$ .<sup>108</sup>

Much of this work has been directed towards materials-based applications, as volatile compounds might be CVD precursors (see *Chemical Vapor Deposition*) and the ability of the thiolates and their fellows to react with the free chalcogens may assist doping lanthanide ions into optical and electrical materials. Thus, thermolysis of the  $[\text{Ln}(\text{SePh})_3(\text{thf})_3]$  ( $\text{Ln} =$

Tm, Ho, Er) gives  $\text{Ln}_2\text{Se}_3$  ( $\text{Ln} = \text{Tm}, \text{Yb}$ ) and a mixture of MSe and  $\text{MSe}_2$  ( $\text{M} = \text{Ho}$ ).

### 3.7.13 Complexes of *N,O*-Donors

*Complexes of Polyaminepolycarboxylic Acids*<sup>4,5</sup>. Ligands like EDTA form stable lanthanide complexes; complexation is facilitated by the considerable entropy change, the enthalpy change being small (and endothermic):

In general, the early lanthanides form triaqua species  $[\text{Ln}(\text{EDTA})(\text{H}_2\text{O})_3]^{3-}$  with nine-coordinate metal (Figure 30), but metals from erbium form eight-coordinate  $[\text{Ln}(\text{EDTA})(\text{H}_2\text{O})_2]^{-}$  following the 'lanthanide contraction'. Thus,  $\text{Na}[\text{Ln}(\text{EDTA})(\text{H}_2\text{O})_3] \cdot 5\text{H}_2\text{O}$  ( $\text{Ln} = \text{La}-\text{Dy}$ ) are isostructural, with nine-coordinate lanthanides; as are  $\text{K}[\text{Ln}(\text{EDTA})(\text{H}_2\text{O})_3]$  ( $\text{Ln} = \text{La}, \text{Nd}$ );  $\text{K}[\text{Yb}(\text{edta})(\text{OH}_2)_2] \cdot 5\text{H}_2\text{O}$  and  $\text{Cs}[\text{Yb}(\text{edta})(\text{OH}_2)_2] \cdot 5\text{H}_2\text{O}$  contain eight-coordinate ytterbium. Comparison with other structures show there to be a dependence upon the alkali-metal cation present in some cases. Thus,  $\text{Cs}[\text{Dy}(\text{edta})(\text{OH}_2)_2] \cdot 3\text{H}_2\text{O}$  and  $\text{Cs}[\text{Ho}(\text{edta})(\text{OH}_2)_2] \cdot 3\text{H}_2\text{O}$  have eight-coordinate lanthanides (unlike the nine-coordinate Na salt), whilst  $\text{Na}[\text{Er}(\text{edta})(\text{OH}_2)_3] \cdot 5\text{H}_2\text{O}$ ,  $\text{K}[\text{Ho}(\text{edta})(\text{OH}_2)_3] \cdot 2\text{H}_2\text{O}$ ,  $\text{Cs}[\text{Nd}(\text{edta})(\text{OH}_2)_3] \cdot 3.5 \text{H}_2\text{O}$ ,  $\text{Cs}[\text{Sm}(\text{edta})(\text{OH}_2)_3] \cdot 4\text{H}_2\text{O}$  and  $\text{Cs}[\text{Gd}(\text{edta})(\text{OH}_2)_3] \cdot 4\text{H}_2\text{O}$  all have nine-coordinate lanthanides. Evidently there is a region towards the end of the lanthanide series where the eight and nine-coordinate anions have similar stabilities, and it is the solubility of the compound that determines which anion is isolated. The EDTA complexes are prototypes for a number of complexes of polyaminepolycarboxylic acids; they are historically important as an early established example of high coordination numbers for lanthanide complexes.

The potentially octadentate DTPA likewise forms stable complexes. These have lately attracted considerable interest with the use of its gadolinium complex as a contrast enhancing agent for body scanners (MRI, see *Metal-based Imaging Agents*), probably the most important new

**Figure 30** The structure of  $\text{La}(\text{EDTA})(\text{H}_2\text{O})_3]^{3-}$

application of lanthanide compounds to emerge in the last 20 years. The introduction of lanthanide-based contrast agents has revolutionised diagnostics, assisting doctors in distinguishing between normal and diseased tissue and thus improving prognosis.

*Magnetic Resonance Imaging and MRI Agents*<sup>109,110</sup>. MRI relies on detecting the NMR signals of water molecules in the body as a function of space. Spatial information is obtained by making the  $^1\text{H}$  resonance frequency position-dependent. The imaging agent enhances the contrast to distinguish between healthy and diseased tissue; the paramagnetic contrast agent, which shortens the relaxation time ( $T_1$ ) for the protons in water molecules in that tissue and enhances the signal intensity. A number of factors have to be taken into account in designing a good MRI agents; they include (a) low toxicity; (b) high magnetic moment; (c) coordinated water molecules; (d) long electron-spin relaxation time; (e) osmolarity similar to serum; (f) water solubility; (g) targeting tissue.  $\text{Gd}^{3+}$  ions have a large number of unpaired electrons ( $S = 7/2$ ) and high magnetic moment, additionally its magnetic properties are isotropic. Its electron-spin relaxation time  $\sim 10^{-9}$  s, and is more suitable than other very paramagnetic lanthanide ions in the second half of the series, such as  $\text{Dy}^{3+}$ ,  $\text{Eu}^{3+}$  and  $\text{Yb}^{3+}$  ( $\sim 10^{-13}$  s). All these magnetic properties are desirable. The toxicity of the gadolinium aqua ion is too great for it to be used directly the LD50 is  $\sim 0.1$  mmol/kg, which is less than the imaging dose, which is normally of the order of 5 g for a human, so complexed  $\text{Gd}^{3+}$  is used, using a ligand that forms a very stable complex in vivo (this can also avoid precipitation as the hydroxide at physiological pH) so a gadolinium complex is used, with a ligand that forms a very stable complex.

Complexes of polyaminocarboxylic acids such as  $[\text{Gd}(\text{DTPA})(\text{H}_2\text{O})]^{2-}$  (Figure 31; gadopentetate dimeglumine; Magnevist) or  $[\text{Gd}(\text{DOTA})(\text{H}_2\text{O})]^{-}$  (gadoterate meglumine;

**Figure 31** The structure of  $\text{Gd}(\text{DTPA})(\text{H}_2\text{O})^{2-}$

Dotarem) have been widely used; these meet most of the above criteria. Both neutral and charged complexes are used, the former having less osmotic effect and the latter being more hydrophilic, so that amide derivatives like [Gd(DTPA-BMA)(H<sub>2</sub>O)] (gadodiamide; Omniscan) have advantages.

This complex again has a nine-coordinate lanthanide; because of the greater denticity of DTPA compared to EDTA, only one water molecule is coordinated in the solid-state structures of Na<sub>2</sub>[Gd(dtpa)(H<sub>2</sub>O)]. Similar ions are present in the Ba[Gd(dtpa)(H<sub>2</sub>O)] and (CN<sub>3</sub>H<sub>6</sub>)<sub>2</sub>[Gd(dtpa)(H<sub>2</sub>O)] and in Ba[Nd(dtpa)(H<sub>2</sub>O)]. On the other hand, a few salts are known, like (NH<sub>4</sub>)<sub>2</sub>[Gd(dtpa)](H<sub>2</sub>O), which have no water coordinated in the solid state. In (NH<sub>4</sub>)<sub>2</sub>[Gd(dtpa)](H<sub>2</sub>O), a hydrogen-bonding network involving the ammonium ions causes Gd(dtpa) units to associate into dimers, in contrast to the monomeric nature of Na<sub>2</sub>[Gd(dtpa)(H<sub>2</sub>O)]. Similarly, Cs<sub>4</sub>[Dy(dtpa)]<sub>2</sub> has an unusual dimeric structure in which Dy is nine-coordinate (as in other dtpa complexes) but with the ninth coordination position occupied by a bridging carboxylate, rather than a water molecule. These disparate solid-state structures reflect the fine balance of forces influencing which species crystallises.

The structure found in salts like Na<sub>2</sub>[Gd(dtpa)(H<sub>2</sub>O)] is thought to represent the species found in solution – data from a number of measurements on solutions containing [Ln(dtpa)(H<sub>2</sub>O)]<sub>n</sub><sup>2-</sup> species, such as luminescence spectra of the Eu and Tb analogues, indicate that one water molecule is coordinated. A wide variety of complexes of amide derivatives of DTPA have also been synthesised, in order to create neutral species.<sup>111,112</sup> Using [Gd(DTPA)(H<sub>2</sub>O)]<sup>2-</sup> it has been shown that these complexes get absorbed by the DNA of the cell they have been used to locate and that they could act as an agent for neutron capture cancer therapy.

Dipicolinates (pyridine-2,6-dicarboxylates) have been investigated in some detail with structures determined for several tris complexes such as Na<sub>3</sub>[Nd(dipic)<sub>3</sub>]·15H<sub>2</sub>O and Na<sub>3</sub>[Yb(dipic)<sub>3</sub>]·13H<sub>2</sub>O, typical of the early and later lanthanides, respectively. The lanthanides have essentially tricapped trigonal prismatic coordination geometries, isostructural along the lanthanide series; they have been the subject of important solution NMR studies. Mono and bis complexes can also be synthesized; the mono complex [Nd(dipic)(H<sub>2</sub>O)<sub>4</sub>] ClO<sub>4</sub> has a polymeric structure in which each picolinate is bound to three different (nine-coordinate) neodymium ions.

### 3.7.14 Other Complexes of *S*-Donors<sup>4,5</sup>

As relatively hard acids, Ln<sup>3+</sup> ions would not be expected to complex readily with soft donor atoms like sulfur. Apart from the thiolates discussed in (see Section ‘Polypyrazolylborates’), several types of complex with chelating ligands such as dithiophosphates and dithiocarbamates have been synthesized by reaction in nonpolar solvents. These fall into two main classes, Ln(S<sub>2</sub>Q)<sub>3</sub> and [Ln(S<sub>2</sub>Q)<sub>4</sub>]<sup>-</sup> (Q = R<sub>2</sub>NC (dithiocarbamate) or R<sub>2</sub>P (dithiophosphate)). Several crystal structures

have been determined; [Ln(S<sub>2</sub>PCy<sub>2</sub>)<sub>3</sub>] (Ln = Sm, Pr) have distorted trigonal prismatic six-coordination, whereas on passing to the Dy and Lu analogs the geometry tends more towards octahedral. In Et<sub>4</sub>N[La(S<sub>2</sub>CNEt<sub>2</sub>)<sub>4</sub>], the geometry is distorted dodecahedral while (Ph<sub>4</sub>P)[Pr(S<sub>2</sub>PMe<sub>2</sub>)<sub>4</sub>] is reported to have a distorted square-antiprismatic coordination geometry. (Ph<sub>4</sub>As)[M(S<sub>2</sub>PEt<sub>2</sub>)<sub>4</sub>] (M = La, Er) have a near-perfect dodecahedral coordination, as does Na [Eu(S<sub>2</sub>CNMe<sub>2</sub>)<sub>4</sub>]. Eight-coordination is also confirmed for (Ph<sub>4</sub>P)[Eu(S<sub>2</sub>P(OEt)<sub>2</sub>)<sub>4</sub>] and [Me<sub>2</sub>NH<sub>2</sub>][Nd(S<sub>2</sub>CNMe<sub>2</sub>)<sub>4</sub>]. A number of adducts have been synthesised in which coordination is primarily by sulphur, Ln(S<sub>2</sub>CNR<sub>2</sub>)<sub>3</sub>(bipy) and Ln(S<sub>2</sub>CNR<sub>2</sub>)<sub>3</sub>(phen); these are discussed in (Section 3.7.10).

A few complexes with sulfur-based crown ether ligands have been characterized, with reaction of LaI<sub>3</sub>(thf)<sub>3</sub> with 9S3 in MeCN affording eight-coordinate [LaI<sub>3</sub>(9S3)(MeCN)<sub>2</sub>].<sup>113</sup>

## 3.8 Coordination Chemistry of the +2 and +4 States

Although relatively limited compared to that of the tripositive metal, these have remained relatively undeveloped until recently; with increasing emphasis on the use of nonaqueous solvents, many discoveries in the +2 state for Eu, Sm, and Yb in particular probably remain to be made.<sup>4,5</sup>

### 3.8.1 The +2 State

The zinc reduction of Eu<sup>3+</sup> to Eu<sup>2+</sup>, followed by its precipitation as the sulfate, is a traditional step in the separation of europium from other lanthanides. In general, the solubilities of the ‘inorganic’ compounds of the Ln<sup>2+</sup> ions resemble those of the corresponding compounds of the alkaline earth metals (insoluble sulfate, carbonate, hydroxide, oxalate). Both europium and the Sm<sup>2+</sup> and Yb<sup>2+</sup> ions can also be prepared by other methods (e.g. electrolysis), although these solutions of the latter two metals tend to be short-lived and oxygen-sensitive in particular. Eu<sup>2+</sup> is the only divalent aqua ion with any real stability in solution. Several divalent lanthanides can, however, be stabilized by the use of nonaqueous solvents such as HMPA and THF, in which they have characteristic colors, quite distinct from those for the isoelectronic trivalent ions on account of the decreased term separations.

### 3.8.2 Complexes

A large number of complexes of O-donors, particularly of SmI<sub>2</sub> have been examined, on account of the widespread use of SmI<sub>2</sub> as a 1-electron reductant in organic synthesis. HMPA has been widely used as the solvent, as it brings about a large increase in rate; HMPA is suspected to be a carcinogen, therefore alternative solvents (and ligands) have been investigated, so the structures of a number of complexes, both of hmpa and other O-donors, have been investigated, shedding light on SmI<sub>2</sub>-promoted reactions. As

a rule, these compounds of amide ligands have a coordination number 6, suggesting steric effects at work, in addition to pointing to strong electron-donating power of the ligands; the coordination number of samarium(II) is usually in the range 7–9. Starting materials for these iodide complexes are usually  $[\text{LnI}_2(\text{thf})_n]$  ( $\text{Ln} = \text{Sm}, \text{Yb}, \text{Eu}$ ) are useful starting materials; these can readily be made from the lanthanide and  $\text{ICH}_2\text{CH}_2\text{I}$ .

Changing reaction conditions and the solvent used can alter the stoichiometry of the product. The initial product of crystallisation of  $\text{SmI}_2$  from thf is pentagonal bipyramidal  $[\text{SmI}_2(\text{thf})_5]$ ; other seven-coordinate complexes obtained using mixtures of thf and dimethoxyethane are  $[\text{SmI}_2(\text{thf})_3(\text{dme})]$  and  $[\text{SmI}_2(\text{thf})(\text{dme})_2]$ .  $\text{YbI}_2$  reacts with 4.5 mols HMPA in thf forming  $[\text{Yb}(\text{HMPA})_4(\text{thf})_2] \text{I}_2$ ; a similar reaction with  $\text{SmI}_2$  affords  $[\text{Sm}(\text{HMPA})_4\text{I}_2]$ . Excess HMPA gives  $[\text{Sm}(\text{HMPA})_6]\text{I}_2$ .  $\text{SmI}_2(\text{thf})_2$  reacts with 2 mols of tetramethylurea forming all-*trans*- $[\text{SmI}_2(\text{tmu})_2(\text{thf})_2]$ , but excess tmu does not replace the other thf ligands. Another complex to be isolated is *trans*- $[\text{SmI}_2(\text{dmi})_4]$  here all the thf groups have been substituted. On the other hand, use of 4 mols (i.e. a deficit on the stoichiometric amount) of dmpu causes displacement of the iodides from  $\text{SmI}_2(\text{thf})_2$  forming  $[\text{Sm}(\text{dmpu})_6] \text{I}_2$  where the cation has a distorted trigonal antiprismatic geometry;  $\text{Sm}-\text{O}$  distances are 2.475–2.488 Å; however, if just 2 mols of dmpu are used in the reaction,  $[\text{SmI}_2(\text{dmpu})_3(\text{thf})]$  results, in which the iodides are *trans*- and the dmpu ligands have a *mer*- arrangement. These compounds all have six-coordinate  $\text{Ln}^{\text{II}}$ . Some simple complexes of *N*-donor ligands have not dissimilar structures.  $[\text{SmI}_2(\text{thf})_2]$  reacts with *N*-methylimidazole (*N*-Meim) forming  $[\text{SmI}_2(\text{N-Meim})_4]$ . On recrystallisation from hot thf, this loses a molecule of *N*-Meim and dimerises, forming  $[\{\text{SmI}(\mu\text{-I})(\text{N-Meim})_3\}_2]$ . Eu behaves similarly in forming  $[\text{EuI}_2(\text{N-Meim})_4]$  and  $[\{\text{EuI}(\mu\text{-I})(\text{N-Meim})_3\}_2]$ .  $\text{LnI}_2$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) reacts with substituted pyridines in thf forming  $[\text{LnI}_2(\text{pyridine})_4]$ ;  $[\text{LnI}_2(3,5\text{-lutidine})_4]$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) and  $[\text{YbI}_2(4\text{-}t\text{-Butpy})_4]$  were determined; all have *trans*-structures.

The developing coordination chemistry of  $\text{Sm}(\text{II})$  has thrown up interesting cases of isomerism. Reaction of  $\text{SmI}_2(\text{thf})_2$  with diglyme results in the isolation of *trans*- $[\text{SmI}_2\{\text{O}(\text{CH}_2\text{CH}_2\text{OME})_2\}_2]$ , whilst the *cis*-isomer was obtained as a by-product in the reaction of  $\text{SmI}_2$  with *t*-BuOK in diglyme. These were the first examples to be isolated of geometric isomers in an eight-coordinate complex.<sup>114</sup> The  $\text{Sm}-\text{O}$  distances in *cis*- $[\text{SmI}_2\{\text{diglyme}\}_2]$ , fall into the range 2.653–2.699 Å, averaging 2.68 Å, which is slightly shorter than the value for the *trans*-isomer. The  $\text{Sm}-\text{I}$  distances in the *cis*-isomer, however, at 3.332–3.333 Å, are significantly longer than those in *trans*- $[\text{SmI}_2\{\text{diglyme}\}_2]$  (3.265 Å). In another study, reaction of  $\text{SmI}_2$  with 1,2-diiodoethane at 50 °C yields  $[\text{SmI}_2(\text{dme})_3]$ . Crystallisation at –20 °C affords racemic  $[\text{SmI}_2(\text{dme})_3]$ , whilst crystallisation from solution at ambient temperature yields a mixture of crystals of the two different enantiomers. It was suggested that interactions between methyl groups prevent ready interconversion.

The ytterbium (II) complex  $[\text{Yb}(\text{NCS})_2(\text{thf})_2]$  exhibits a rich range of oxidative addition reactions<sup>115</sup> affording complexes such as  $\text{Yb}(\text{NCS})_3(\text{thf})_4$ ,  $\text{Yb}(\text{NCS})_3(\text{Odpp})(\text{thf})_3$  ( $\text{HOdpp} = 2,6\text{-diphenylphenol}$ ), and  $\text{Yb}(\text{NCS})_2(\text{Cp})(\text{thf})_3$ . It reacts with  $\text{CCl}_3\text{CCl}_3$  forming  $\text{Yb}(\text{NCS})_2\text{Cl}(\text{thf})_4$ , which turns out to have the solid-state structure  $[\text{YbCl}_2(\text{thf})_5]^+ [\text{Yb}(\text{NCS})_4(\text{thf})_3]^-$  in contrast to the monomer  $\text{Yb}(\text{NCS})_3(\text{thf})_4$ . Oxidation of  $\text{Yb}(\text{NCS})_2(\text{thf})_2$  with  $\text{TiO}_2\text{CPh}$  initially affords a solvated form of  $\text{Yb}(\text{NCS})_2(\text{O}_2\text{CPh})$  which then gives a mixture of  $\text{Yb}(\text{NCS})_3(\text{thf})_4$  and dimeric  $[\{\text{Yb}(\text{NCS})(\text{O}_2\text{CPh})_2(\text{thf})_2\}_2]$ . The thf ligands in  $\text{Yb}(\text{NCS})_2(\text{thf})_2$  can be replaced by dme forming 8-coordinate  $\text{Yb}(\text{NCS})_2(\text{dme})_3$ .

The first simple  $\text{Tm}(\text{II})$ ,  $\text{Nd}(\text{II})$  and  $\text{Dy}(\text{II})$  complexes have been synthesised recently. Reaction of Nd and Dy with  $\text{I}_2$  at 1500 °C followed by dissolution of the product affords  $[\text{LnI}_2(\text{dme})_3]$  and  $[\text{LnI}_2(\text{thf})_5]$  ( $\text{Ln} = \text{Nd}, \text{Dy}$ ).  $[\text{NdI}_2(\text{thf})_5]$  has the familiar pentagonal bipyramidal structure with axial iodines.  $[\text{TmI}_2(\text{dme})_2(\text{thf})]$  has a similar coordination geometry.<sup>116</sup>

Among complexes with multidentate ligands, a few lanthanide(II) diketonates are known.  $[\text{Eu}(\text{tmhd})_2(\text{dme})_2]$ , has been made by reaction of  $[\text{EuI}_2(\text{thf})_2]$  with Kthd in thf, evaporation and crystallisation from DME;  $[\text{Sm}(\text{tmhd})_2(\text{dme})_2]$  is made by a similar route.

A number of crown ether complexes exist. Thus  $[\text{Eu}(\text{benzo-15-crown-5})_2] (\text{ClO}_4)_2$  has been synthesised by electrochemical reduction of a solution of  $\text{Eu}(\text{ClO}_4)_3$  and benzo-15-crown-5 in  $\text{MeOH}/\text{H}_2\text{O}$ . It contains 10-coordinate europium, with  $\text{Eu}-\text{O}$  distances in the range 2.662 (3)–2.728 (4) Å. This compound exhibits strong luminescence, taking on a violet hue in daylight.  $[\text{Eu}(\text{12-crown-4})(\text{H}_2\text{O})_3\text{Cl}]\text{Cl}$  has eight-coordinate Eu; europium is 10-coordinate in the  $[\text{Eu}(\text{15-crown-5})_2]^{2+}$  ion and in  $[\text{Eu}(\text{18-crown-6})(\text{ClO}_4)_2]$ . Two  $\text{Sm}(\text{II})$  complexes have been made.  $[\text{Sm}(\text{15-crown-5})_2] (\text{ClO}_4)_2$  has a sandwich structure with samarium bound to two 15-crown-5 molecules, whilst in  $[\text{Sm}(\text{18-crown-6})(\text{ClO}_4)_2]$  the metal cation is again 10-coordinate, bound to six oxygen atoms of the crown ligand and four oxygen atoms from two perchlorates.<sup>117</sup>

The  $\text{Eu}(\text{II})$  edta complex  $\text{Na}_3[\text{Eu}(\text{edta})]\text{Cl}\cdot 7\text{H}_2\text{O}$  is in fact polymeric in the solid state with europium bound to two nitrogens and to six carboxylate oxygens.  $[(\text{NH}_2)_3]_3[\text{Eu}^{\text{II}}(\text{dtpa})(\text{H}_2\text{O})]\cdot 8\text{H}_2\text{O}$  is isostructural with the Sr analogue. Perhaps unexpectedly, in solution,  $[\text{Eu}^{\text{II}}(\text{dtpa})(\text{H}_2\text{O})]^{3-}$  is less stable to oxidation than  $\text{Eu}^{2+}(\text{aq})$ .

A number of aryloxides employing bulky ligands have been explored in some detail. The thf adducts  $\text{Yb}(\text{O}2,6\text{-Bu}'_2\text{-4-Me-C}_6\text{H}_2)_2(\text{thf})_2$  are tetrahedral while  $\text{Yb}(\text{O}2,6\text{-Bu}'_2\text{-4-Me-C}_6\text{H}_2)_2(\text{thf})_3$  are five-coordinate with square-pyramidal structures.  $[\text{Sm}(\text{O-2,6-Bu}'_2\text{C}_6\text{H}_3)_2(\text{thf})_3]\cdot \text{thf}$  and  $[\text{Sm}(\text{OC}_6\text{H}_3\text{Bu}'_2\text{-2,6-Me-4})_2(\text{thf})_3]$  are both five-coordinate trigonal bipyramidal.

The bis(silylamide) complexes  $\text{Ln}\{\text{N}(\text{SiMe}_3)_2\}_2$  and their adducts with Lewis bases such as thf and tertiary phosphines

tend to be three- and four-coordinate.  $\text{Yb}\{\text{N}(\text{SiMe}_3)_2\}_2$  is a dimer with two bridging alkylamides, giving three-coordinate and  $[\text{Eu}\{\text{N}(\text{SiMe}_3)_2\}_3]^-$  likewise is three-coordinate (surprisingly, planar, unlike the  $\text{Eu}^{\text{III}}$  analog), while  $\text{M}\{\text{N}(\text{SiMe}_3)_2\}_2\text{L}_2$  ( $\text{L} = \text{PBu}_3$ ,  $\text{thf}$ ;  $\text{L}_2 = \text{dmpe}$ ) are four-coordinate and  $\text{Eu}\{\text{N}(\text{SiMe}_3)_2\}_2(\text{glyme})_2$  is six-coordinate.  $[\text{Sm}(\text{N}(\text{SiMe}_3)_2)_2(\text{thf})_2]$  has significant short-Sm...C distances, evidence for agostic interactions (*see Agostic Bonding*). In  $[\text{Sm}(\text{NPh}_2)_2(\text{thf})_4]$ , the coordination geometry approximates to trigonal prismatic (*see Trigonal Prism*).

Polypyrazolylborates have been extensively investigated.<sup>104</sup>  $[\text{Ln}(\text{Tp})_2(\text{thf})_2]$  and  $[\text{Ln}(\text{Tp}^{\text{Me}_2})_2]$  ( $\text{Ln} = \text{Eu}$ ,  $\text{Sm}$ , and  $\text{Yb}$ ) have been synthesised; the latter are very insoluble and are usually purified by sublimation in the cases of the  $\text{Eu}$  and  $\text{Yb}$  compounds. The six-coordinate  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2]$  undergoes a range of 1- electron transfer reactions. In its wide range of oxidations, it forms  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2\text{X}]$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ,  $\text{F}$ ) by halogen abstraction from organic compounds, and  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2]$  I by iodine oxidation. Reaction with  $\text{TiBPh}_4$  gives  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2]\text{BPh}_4$ .  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2]$  cleaves dichalcogenides  $\text{REER}$  forming  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2(\text{ER})]$  ( $\text{R}$  e.g.  $\text{Ph}$ ,  $\text{E} = \text{S}$ ,  $\text{Se}$ ), and reacts with azobenzene forming  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2(\text{N}_2\text{Ph}_2)]$  where the  $\text{Tp}^{\text{Me}_2}$  ligands remain tridentate.  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2]$  reacts with dioxygen forming the first lanthanide superoxo complex  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2(\eta^2\text{-O}_2)]$ . It undergoes a one-electron oxidation with  $[\text{Hg}(\text{C}\equiv\text{CPh})_2]$  forming monomeric seven-coordinate  $[\text{Sm}(\text{Tp}^{\text{Me}_2})_2(\text{C}\equiv\text{CPh})]$ . Using the bulkier hydrotris(*3-t*-butyl-5-methylpyrazolyl) borate ligand ( $\text{Tp}^{\text{tBu,Me}}$ ), it is still possible to obtain bis complexes with  $\text{Tp}^{\text{tBu,Me}}$ , but  $[\text{Ln}(\text{Tp}^{\text{tBu,Me}})_2]$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Yb}$ ) shows two different mode of ligand bonding; one is a conventional  $\eta^3$ -ligand, the other is bound via two nitrogen atoms and an agostic  $\text{B-H}\cdots\text{Sm}$  interaction. The NMR spectrum of  $[\text{Yb}(\text{Tp}^{\text{tBu,Me}})_2]$  shows  $^{171}\text{Yb}$ -HB coupling, confirming that the agostic interaction persists in solution.

A number of organophosphides and organoarsenides of divalent lanthanides have been synthesised, with a certain similarity to the amides.  $[\text{YbI}_2(\text{thf})_2]$  and  $[\text{Yb}\{\text{N}(\text{SiMe}_3)_2\}_2(\text{thf})_2]$  react with  $\text{KPPH}_2$  forming  $[\text{Yb}(\text{PPh}_2)_2(\text{thf})_4]$ ; the  $\text{thf}$  can be displaced by *N*-methylimidazole forming *trans*- $[\text{Yb}(\text{PPh}_2)_2(\text{N-Methylimidazole})_4]$ . These compounds, together with  $[\text{Eu}(\text{PPh}_2)_2(\text{N-Methylimidazole})_4]$ ,  $[\text{Sm}(\text{PPh}_2)_2(\text{N-Methylimidazole})_4]$ ,  $[\text{Yb}(\text{P}(\text{mesityl})_2)_2(\text{thf})_4]$ ,  $[\text{Sm}(\text{P}(\text{mesityl})_2)_2(\text{thf})_4]$  and  $[\text{Sm}(\text{As}(\text{mesityl})_2)_2(\text{thf})_4]$  all having trans-octahedral structures.

Some compounds with heavier group 16 donor atoms have lately been reported, of the type  $\text{Yb}(\text{SAr})_2(\text{DME})_2$  (six-coordinate) and  $\text{Ln}(\text{QMe})_2(\text{thf})_n$  ( $\text{Ln} = \text{Yb}$ ,  $\text{Sm}$ ,  $\text{Eu}$ ;  $\text{Q} = \text{Se}$ ,  $\text{Te}$ ). Transmetallation of  $\text{Sm}$  and  $\text{Eu}$  with  $\text{Hg}(\text{SC}_6\text{F}_5)_2$  affords  $\text{Sm}(\text{SC}_6\text{F}_5)_3$  and  $\text{Eu}(\text{SC}_6\text{F}_5)_2$  respectively; these have the solid-state structures  $[(\text{thf})_2\text{Sm}(\mu_2\text{-SC}_6\text{F}_5)(\text{SC}_6\text{F}_5)_2]_2$  and  $[(\text{thf})_2\text{Eu}(\mu_2\text{-SC}_6\text{F}_5)_2]_n$ , the latter being a 1-dimensional polymer; these undergo thermal decomposition to  $\text{LnF}_3$ . Ytterbium reacts with organic disulphides forming  $[\text{Yb}(\text{SAr})_2(\text{py})_2]$  ( $\text{Ar} = 2,4,6\text{-triisopropylphenyl}$ ). A sterically crowded  $\text{Yb}^{\text{II}}$  thiolate  $[\text{Yb}(\text{SAr}^*)_2(\text{thf})_4]$  ( $\text{Ar}^* = 2,6\text{-Trip}_2\text{C}_6\text{H}_3$ , where  $\text{Trip}$

is  $2,4,6\text{-iPr}_3\text{C}_6\text{H}_2$ ) has the trans-structure now becoming familiar for these  $\text{Ln}^{\text{II}}$  systems. The overcrowding caused by the sterically encumbered  $\text{Ar}^*$  ligands is reflected in the large  $\text{Yb-S-C}$  angle of  $151.16^\circ$ . The unsolvated compound is formally two-coordinate, but there are  $\eta^6\text{-}\pi$ -interactions present. Lanthanide(II) selenolate and tellurolate complexes, usually obtained as etherates, are possible precursors to lanthanide monochalcogenides.  $\text{M}(\text{TePh})_2$  ( $\text{M} = \text{Yb}$ ,  $\text{Eu}$ ) crystallize as 1-dimensional polymers like  $[(\text{thf})_2\text{Eu}(\text{TePh})_2]_\infty$  and  $[(\text{thf})_2\text{Yb}(\text{TePh})_2\cdot 0.5(\text{thf})]_\infty$ .  $[\text{Ln}(\text{ESi}(\text{SiMe}_3)_3)_2(\text{tmeda})_2]$  ( $\text{Ln} = \text{Eu}$ ,  $\text{Yb}$ ;  $\text{E} = \text{Se}$ ,  $\text{Te}$ ) have been reported; the ytterbium tmeda complexes eliminate  $\text{E}(\text{Si}(\text{SiMe}_3)_3)_2$  at  $200^\circ\text{C}$  affording  $\text{YbSe}$  and  $\text{YbTe}$ .  $\text{Ln}(\text{SePh})_2$  reacts with selenium (rather as the trivalent analogues do) in  $\text{dme}$  forming heterovalent clusters  $[\text{Ln}_4\text{Se}(\text{SePh})_8(\text{dme})_4]$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Yb}$ ,  $\text{Nd}^{\text{III}}$ / $\text{Yb}^{\text{II}}$ ,  $\text{Sm}^{\text{III}}$ / $\text{Yb}^{\text{II}}$ ) which contain a square of lanthanide ions with a capping selenide.

A variety of halometallates exist. For example,  $\text{Rb}_4\text{TmI}_6$ , synthesised by heating a mixture of  $\text{RbI}$ ,  $\text{Tm}$ , and  $\text{HgI}_2$ , has the  $\text{K}_4\text{CdI}_6$  structure with trigonal antiprismatic coordination of  $\text{Tm}$ .  $\text{RbYbI}_3$  has a structure based on edge-sharing  $[\text{YbI}_6]$  octahedra. Reduction of  $\text{MX}_3$  ( $\text{M} = \text{Sm}$ ,  $\text{Dy}$ ,  $\text{Tm}$ ,  $\text{Yb}$ ;  $\text{X} = \text{Br}$ ,  $\text{I}$ ) with alkali metals,  $\text{In}$  and  $\text{Tl}$  ( $\text{A}$ ) leads in general to the ternary compounds  $\text{AMX}_3$  and  $\text{AM}_2\text{X}_5$ ; some similar compounds with divalent metals ( $\text{Ca}$ ,  $\text{Sr}$ ,  $\text{Ba}$ ) have also been made.  $\text{LiDy}_2\text{Br}_5$ , prepared by reduction of  $\text{DyBr}_3$  with  $\text{Li}$  metal at  $700^\circ\text{C}$ , is isostructural with  $\text{LiDy}_2\text{Cl}_5$ ,  $\text{LiYb}_2\text{Cl}_5$  and  $\text{LiLn}_2\text{Br}_5$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Tm}$ ).

### 3.8.3 The +4 State

Cerium is the only lanthanide with an extensive chemistry in this oxidation state. The cerium(+4) aqua ion, obtained by acid dissolution of  $\text{CeO}_2$ , is thermodynamically unstable ( $E = 1.6\text{ V}$  in  $1\text{ M HNO}_3$ ); the reduction potential is anion-sensitive, indicating that complexes are present rather than a simple aqua ion. The salts  $\text{Ce}(\text{NO}_3)_4\cdot 5\text{H}_2\text{O}$  and  $\text{CeSO}_4\cdot 4\text{H}_2\text{O}$  can be crystallized from solution, the former probably having 11-coordinate  $\text{Ce}(\text{NO}_3)_4(\text{H}_2\text{O})_3$  molecules like the thorium analog. The most familiar nitrate complex is  $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$ , a traditional oxidizing agent in titrimetry and in organic chemistry as well as a convenient synthetic starting material. The  $\text{Ce}(\text{NO}_3)_6^{2-}$  ion has 12-coordinate cerium while cerium is 10-coordinate in the  $\text{Ce}(\text{CO}_3)_5^{6-}$  ion.  $\text{MgCe}(\text{NO}_3)_6\cdot 8\text{H}_2\text{O}$  and  $\text{K}_2\text{Ce}(\text{NO}_3)_6$  containing 12-coordinate  $[\text{Ce}(\text{NO}_3)_6]^{2-}$  ions too. Hydrated cerium(IV) triflate dehydrates on stirring with triflic anhydride. It is potentially a valuable source of other  $\text{Ce}^{\text{IV}}$  compounds. The iodates  $\text{Ce}^{\text{IV}}\text{HIO}_6\cdot 4\text{H}_2\text{O}$  and  $\text{M}\text{Ce}^{\text{IV}}\text{IO}_6\cdot n\text{H}_2\text{O}$  ( $\text{M} = \text{alkali metal}$ ) have also been made.

A number of fluoride complexes have been made, both by crystallization for the ammonium salts like  $(\text{NH}_4)_4\text{CeF}_8$ , which has square-antiprismatic coordination of cerium, also found in the  $(\text{CeF}_6^{2-})_\infty$  chains in  $(\text{NH}_4)_2\text{CeF}_6$ , its thermal decomposition product.  $(\text{NH}_4)_3\text{CeF}_7\cdot \text{H}_2\text{O}$  acquires dodecahedral eight-coordination by dimerization.  $(\text{NH}_4)_4[\text{CeF}_8]$  can

also be made by fluorination of cerium oxide with  $\text{NH}_4\text{HF}_2$ . Alkali-metal cerates  $\text{M}_2\text{CeF}_6$  and  $\text{M}_3\text{CeF}_7$  ( $\text{M}$  = alkali metal) are moisture sensitive and are made by fluorination of  $\text{MCl}/\text{CeO}_2$  mixtures. Several hexachlorocerate(IV) salts are known, perhaps the most convenient starting material for further syntheses being the  $(\text{H}_2 \text{ diglyme}_3)^+$  salt, made from the reaction of  $\text{CeO}_2$  with  $\text{SOCl}_2$  in diglyme; these react with  $\text{HBr}$  to give moisture-sensitive  $\text{CeBr}_6^{2-}$  salts.  $\text{Ce}^{\text{IV}}$  is presumably too strongly oxidizing to coexist with  $\text{I}^-$  as no corresponding iodocerates have been made.

A number of neutral complexes of O-donor Lewis bases have been made, such as 10-coordinate  $\text{Ce}(\text{NO}_3)_4(\text{Ph}_3\text{PO})_2$ , and octahedral  $\text{CeCl}_4\text{L}_2$  ( $\text{L}$  =  $\text{Ph}_3\text{PO}$ ,  $\text{Ph}_3\text{AsO}$ ,  $\text{HMPA}$ , urea,  $t\text{-Bu}_2\text{SO}$ ). The  $\text{Ph}_3\text{PO}$  complex is *cis*, like the uranium analog, while X-ray diffraction study of the (*trans*)  $\text{HMPA}$  complex shows a close structural correspondence to the corresponding  $\text{U}^{\text{IV}}$  compound.

Cerium(III) tris( $\beta$ -diketonate) complexes are readily oxidized to the cerium(IV) compounds. They are volatile with vapor pressures high enough for MOCVD use. A number of diketonates are now better characterised, prompted by the possibility of using them as CVD materials and petrol additives, as well as a source of cerium oxide as an oxygen store for catalytic converters.  $[\text{Ce}\{\text{Me}_3\text{CCOCHCOCH}_2(\text{OMe})_2\}_4]$ ,  $\text{Ce}(\text{acac})_4$  (Figure 32),  $\text{Ce}(\text{dbm})_4$ ,  $[\text{Ce}(\text{pmhd})_4]$ , and  $\text{Ce}(\text{tmhd})_4$  all have square-antiprismatic coordination of cerium (in the  $[\text{Ce}(\text{catecholate})_4]^{4-}$  ion the coordination is dodecahedral).

The alkoxides  $\text{Ce}(\text{OR})_4$  are another well-developed class of  $\text{Ce}^{\text{IV}}$  compounds. The alkoxide group plays an important role in stabilising the  $\text{Ce}(\text{IV})$  state, witness the existence of  $[\text{CeCp}_2(\text{OBu}^t)_2]$  and  $[\text{CeCp}_3(\text{OBu}^t)]$ , when other  $\text{Ce}(\text{IV})$  organometallics cannot be isolated. The isopropoxide is volatile in vacuo below  $200^\circ\text{C}$  (its bis(isopropanol) adduct has six-coordinate cerium). General methods are available to

make many  $\text{Ce}(\text{OR})_4$  ( $\text{R}$  e.g.  $\text{Me}$ ,  $\text{Et}$ ,  $\text{OPr}^i$ ,  $n\text{-C}_8\text{H}_{17}$ ):-

As usual, many of these are oligomers, though coordinative saturation can be achieved by adduct formation. Crystals of  $[\text{Ce}(\text{OSiPh}_3)_4(\text{DME})]$  display octahedral coordination of cerium with  $\text{Ce}-\text{O}(\text{Si})$  2.10–2.14 Å and two rather long  $\text{Ce}-\text{O}(\text{ether})$  bonds at 2.58–2.59 Å. Although the solid is air- and moisture-stable, it undergoes immediate reaction with  $\text{Hacac}$  forming  $\text{Ce}(\text{acac})_4$ . Thermal desolvation of  $[\text{Ce}(\text{OPr}^i)_4(\text{HOPr}^i)_2]$  affords  $[\text{Ce}_4\text{O}(\text{OPr}^i)_{14}]$ , which has the structure  $[\text{Ce}_4(\mu_4\text{-O})(\mu_3\text{-OPr}^i)_2(\mu\text{-OPr}^i)_8(\text{OPr}^i)_{14}]$ .  $(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$  reacts with  $\text{NaOCMe}_3$  forming various products, including  $\text{Na}_2\text{Ce}(\text{OCMe}_3)_6(\text{DME})_2$  which has octahedral  $[\text{Ce}(\text{OCMe}_3)_6]^{2-}$  ions surrounded by  $\text{Na}(\text{DME})^+$  ions.

The first  $\text{Ln}(\text{IV})$  amides have been made.<sup>118</sup> Although it cannot be oxidised with  $\text{Cl}_2$ ,  $[\text{Ce}(\text{N}(\text{SiMe}_3)_2)_3]$  reacts with  $\text{TeCl}_4$  forming  $[\text{CeCl}(\text{N}(\text{SiMe}_3)_2)_3]$ ; this has a trigonal pyramidal structure, with  $\text{Ce}$  0.36 Å out of the  $\text{N}_3$  basal plane (and, interestingly a 0.05 Å lengthening of the  $\text{N}-\text{Si}$  bond).  $\text{PPh}_3\text{Br}_2$  reacts with  $[\text{Ce}(\text{N}(\text{SiMe}_3)_2)_3]$  forming the isostructural  $[\text{CeBr}(\text{N}(\text{SiMe}_3)_2)_3]$ . Another  $\text{Ce}(\text{IV})$  amide was synthesised by iodine oxidation of a cerium(III) compound of a triamidoamine, affording a notable compound with a rare  $\text{Ce}^{\text{IV}}\text{-I}$  linkage; analogous oxidation with  $\text{X}_2$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ) yields mixed-valence dimers (Figure 33).<sup>119</sup>

2,4,6-tri-*t*-butylpyridyl-1,3,5-triazine ( $\text{L}$ ) reacts with  $(\text{NH}_4)_2[\text{Ce}(\text{NO}_3)_6]$  forming 11-coordinate  $[\text{Ce}(\text{L})(\text{NO}_3)_4]$ . In contrast to the other lanthanides, cerium forms genuine bis(porphyrin) and bis(phthalocyanine) complexes with the metal in the +4 oxidation state. Solution NMR shows that the two porphyrin rings do not rotate with respect to each other even at  $140^\circ\text{C}$ .

#### 4 PROMETHIUM

On account of this element's rarity, a separate account of it is desirable.<sup>120,121</sup> Although the existence of promethium was predicted as early as 1913, it was not definitely discovered until 1945, since all isotopes are radioactive with the longest-lived isotope having a half-life of 17.7 years (<sup>145</sup>Pm). It is a fission product of <sup>238</sup>U and is thus obtained on work-up of reprocessing wastes.

Although early attempts to identify it in lanthanide ores were not successful, it has been detected at the level of  $4 \times 10^{-15}$  g kg<sup>-1</sup> in Congolese pitchblende. It has also been detected at a low level in apatite ( $10^{-11}$  g from 6 million kg mineral), although it may have originated there from neutron irradiation of neodymium or by spontaneous fission of <sup>238</sup>U.

Relatively little is known about the chemistry of promethium, although the established facts highlight the resemblance of promethium to the lanthanides that flank it. The halides are well defined, and have been shown to have the expected structures (Table 2). Thus in a recent study, starting with some 100 µg of Pm<sub>2</sub>O<sub>3</sub>, the halides were synthesized microchemically, using the reaction with fluorine for PmF<sub>3</sub> and the reaction with HX (X = Cl, Br) for the chloride and bromide; the latter two reacted with HI to give the iodide. Pm<sub>2</sub>O<sub>3</sub> is one of the few lanthanide oxides to crystallize in three modifications.<sup>122</sup>

It would be expected that promethium would form some stable compounds in the +2 oxidation state, but no definite evidence has yet been obtained since studies have been hindered both by the small quantities available and by its radioactivity.

#### 5 LANTHANIDES IN ORGANIC SYNTHESIS

Lanthanide complexes have increasingly been used as reagents,<sup>123,124</sup> two of the main areas being SmI<sub>2</sub> as a one-electron reducing agent<sup>125,126</sup> and the use of lanthanide triflates (and scandium triflate especially) as reusable water-soluble Lewis Acid catalysts.<sup>127,128</sup>

#### 6 USES OF THE LANTHANIDES<sup>3,129,130</sup>

There are increasingly numerous uses of these metals that make use of particular electronic, magnetic, and optical properties of individual lanthanides; most current applications involve the earlier rather than the later metals, there being no major uses for the metals Ho–Lu at present.

The main optical uses are in lasers, phosphors, and lenses. The single most important phosphors contain europium(III) in a yttrium host such as Y<sub>2</sub>O<sub>2</sub>S, which is used for the

red phosphor in TV color screens; other phosphors are used (Tm, Tb) in X-ray image intensifying screens. Neodymium-doped yttrium–aluminum garnet (YAG) is an important laser material, whilst erbium-YAG lasers are starting to be used in cosmetic skin resurfacing. Erbium-doped fibre amplifiers are becoming significant in telecommunications. Neodymium-containing glass is used in protective goggles, owing to its absorption around 580 nm. while La<sub>2</sub>O<sub>3</sub> is used in manufacturing optical glass of a high refractivity. CeO<sub>2</sub> is used in polishing glass and also in decolourising glass.

Principal magnetic uses employ either the samarium–cobalt or Nd<sub>2</sub>Fe<sub>14</sub>B permanent magnet materials. The latter give slightly stronger products and employ materials with more assured supply, but the samarium magnets can be used at much higher temperatures.

There are a number of current optical and magnetooptical applications and several at the development stage. The use of LaB<sub>6</sub> in electron guns has long been established, as has that of yttrium–iron garnet (YIG) in microwave devices, while gadolinium–gallium garnet is used for bubble memory storage devices. Developing uses include yttrium-stabilized zirconia (YSZ) in particular as a solid electrolyte and as an oxygen-sensor in automobile exhaust systems, rare-earth-doped barium titanates in thermistors, and LaNi<sub>5</sub> in rechargeable batteries. Yttrium–barium copper oxide and other lanthanide-containing oxides are likely to become important commercially in warm superconductors.

Probably the biggest use in terms of quantity is that of lanthanide-exchanged zeolites as cracking catalysts in the petrochemical industry (mainly La and Ce), using about 500 t a day in the USA alone.

Because of its high refractive index and hardness, YSZ is a superior material for artificial diamonds to YAG, also used for this purpose. The praeodymium–neodymium mixture known as didymium is traditionally used to color welders' goggles (as well as a strengthening agent for Mg-based alloys). Several lanthanide oxides, particularly Nd<sub>2</sub>O<sub>3</sub>, are used as glass-coloring agents. CeO<sub>2</sub> has been used as an ingredient of automobile catalytic converters and in self-cleaning ovens as an oxidation catalyst whose oxygen storage role is presumably a consequence of the ability of cerium to switch oxidation states.

Medical applications are so far limited in number, but gadolinium complexes of DTPA and other ligands have become highly important injectible MRI contrast agents (*see Metal-based Imaging Agents*). The luminescent properties of the lanthanides are becoming exploited in luminescent sensors and bioassays.

#### 7 TOXICITY OF THE LANTHANIDES<sup>35,131</sup>

The lanthanides are generally not regarded as particularly toxic. Studies on animals indicate that the toxicity depends

on how the lanthanide was introduced. Little appears to be absorbed in oral ingestion although it appears considerably more toxic in intravenous administration. Inhalation of vapor and dust should be avoided as solid compounds if inhaled tend to remain in the lungs and are only slowly ingested on account of their insolubility (This could be an occupational hazard in lanthanide refining and in 'new' lanthanide industries.) Lanthanides tend to accumulate in the liver, spleen, kidneys, and bone.

The use of complexed  $Gd^{3+}$  in MRI relies on the high stability of the  $Gd$ -DTPA complex to maintain an extremely low level of free  $Gd^{3+}$ , but some side-effects have been observed using such ionic compounds, prompting current research to produce nonionic contrast agents.

## Abbreviations

Cp = cyclopentadienyl ( $C_5H_5$ ); Cp' = general substituted or unsubstituted Cp; Cp\* = pentamethylcyclopentadienyl ( $C_5Me_5$ );  $X_nCp$  = Cp with  $n$  Hs substituted by X; Ind = indenyl ( $C_9H_7$ ); COT = cyclooctatetraenyl ( $C_8H_8$ ); Mes = mesityl ( $C_6H_2Me_3$ ); Cy = cyclohexyl  $C_6H_{11}$ ; Ln = lanthanide and group 3 metals.

## 1 INTRODUCTION

Organometallic compounds of the rare earth metals have been a curiosity till only a few decades ago. That changed in the last 20 years of the twentieth century after the availability of modern preparative and analytical techniques and with the discovery of the high potential of those compounds,

which are all extremely sensitive to oxygen and water, as reagents in organic synthesis and as very active catalysts. Following the discovery of the tricyclopentadienyl derivatives of the lanthanides by *Wilkinson* and *Birmingham* in 1954,<sup>1</sup> most of the organolanthanide compounds prepared during the first 20 years have been sandwich complexes (*see Sandwich Compound*), containing unsubstituted or substituted cyclopentadienyl ligands. In contrast, cyclopentadienyl-free organolanthanide compounds, like alkyl or aryl derivatives, alkenyl, alkynyl, allyl, hydrido, and carbene complexes, as well as cyclooctatetraenyl, pentadienyl derivatives, and lanthanidocenes with nitrogen and phosphorus containing heterocycles, which are incredibly active catalysts, developed new fields in organolanthanide chemistry recently, establishing a new area of organometallic chemistry.

The research in this field has been well documented in review articles<sup>2–6</sup> and a book.<sup>7</sup> Recent reviews concerning the state of the art in 2002 can be found in the special issue of *Chemical Reviews: Frontiers in Lanthanide Chemistry*.<sup>8</sup>

This article discusses the preparation, structure, and chemistry of rare earths complexes with bonds to carbon. An emphasis is given to compounds prepared and characterized after EIC1 appeared in 1994 up to the end of 2003, but only papers, which appeared after 2000, are cited in the reference list. Inorganic compounds that may be bonded through carbon, such as carbides (*see Carbides: Transition Metal Solid-state Chemistry*) or cyanides (*see Cyanide Complexes of the Transition Metals and Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry*), are also excluded as well as the chemistry of rare earth cations with organic compounds in the gas phase. While at the moment of finishing this chapter for EIC-I most organo rare earth complexes have been cyclopentadienyl derivatives, the development of this area of organometallic chemistry produced new classes of compounds in the common oxidation state Ln(III) as well as in the more unusual oxidation states Ln(0), Ln(I), Ln(II), and Ln(IV) in recent years. Therefore the organization of this chapter is somewhat different compared to EIC1. The use of organolanthanides as reagents in organic synthesis as well as in catalysis is not covered here, although Ln to carbon bonds may be involved in these processes. Those subjects have been treated in comprehensive book articles recently, for example, for organolanthanides in organic synthesis<sup>9</sup> and in catalysis.<sup>10</sup>

## 2 LANTHANIDE COMPLEXES WITH $\sigma$ -BONDED HYDROCARBYL LIGANDS

Over the years the homoleptic (*see Homoleptic Compound*) alkyl and aryl complexes were one of the major challenges in organolanthanide chemistry. The simplest organometallic

compounds of the rare earths are the solvated or solvent-free species  $\text{LnR}_2$  or  $\text{LnR}_3$  with the rare earth metals in their common oxidation states  $\text{Ln}^{2+}$  and  $\text{Ln}^{3+}$ . This is usually insufficient to meet the lanthanides' demands of steric saturation through high coordination numbers. The isolation and characterization of compounds belonging to this class were achieved using bulky alkyl ligands. When less bulky alkyl ligands are used, *ate* complexes containing more than three alkyl ligands attached to the metal  $[\text{R}_{3+n}\text{Ln}]^{n-}$  are often formed. Mono- and dialkyl complexes of the lanthanides are more frequent than homoleptic complexes, because in those cases the bulky ancillary ligands were usually used for the coordinative saturation of the metal center. This section deals only with  $\text{Ln}(\text{III})$ -alkyl derivatives, for alkyl complexes of the divalent lanthanides see Section 11. Two reviews appeared for work up to 1994<sup>3</sup> and up to 2001.<sup>11</sup>

## 2.1 Complexes with Three and More $\sigma$ -Bonded Hydrocarbyls

The reactions of  $\text{LnCl}_3$  ( $\text{Ln} = \text{Y}, \text{La}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Gd}, \text{Tb}, \text{Dy}, \text{Ho}, \text{Er}, \text{Tm}, \text{Yb}, \text{Lu}$ ) with  $\text{MeLi}$  in  $\text{Et}_2\text{O}$  in the presence of TMEDA or DME yields *ate* complexes  $[\text{Li}(\text{L})]_3[\text{LnMe}_6]$  ( $\text{L} = \text{TMEDA}, \text{DME}$ ) (equation 1).

The crystal structure of  $[\text{Li}(\text{TMEDA})]_3[\text{LnMe}_6]$  ( $\text{Ln} = \text{Ho}, \text{Er}$ ) and  $[\text{Li}(\text{DME})]_3[\text{LuMe}_6]$  shows an octahedral  $\text{LnMe}_6$  arrangement with Me bridges to the Li atoms (Figure 1). Alkylation of  $(\text{L})\text{LnCl}_3$  ( $\text{Ln} = \text{Sc}, \text{Y}$ ;  $\text{L} = 1,4,7\text{-trimethyl-1,4,7-triazacyclononane}$ ) with  $\text{MeLi}$  in THF gives the corresponding species  $(\text{L})\text{Ln}(\text{CH}_3)_3$ , and the reaction of  $\text{LuCl}_3$  with  $\text{NaCp}^*$  and  $\text{LiMe}$  in THF in the presence of TMEDA yields  $[\text{Li}(\text{TMEDA})_2][\text{Cp}^*\text{LuMe}_3]$ , showing the Lu atom tetrahedrally coordinated by the  $\text{Cp}^*$  ring and the three Me groups.<sup>11</sup>

Homoleptic (*see Homoleptic Compound*) complexes  $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_n$  ( $\text{M} = \text{Sm}, \text{Y}, n = 3$ ;  $\text{Tb}, \text{Er}, \text{Yb}, \text{Lu}, n = 2$ ) were prepared by the reactions of the respective  $\text{LnCl}_3$  with  $\text{Me}_3\text{SiCH}_2\text{Li}$  in THF (equation 2 and 3).  $\text{Yb}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  and the related neopentyl derivative  $\text{Yb}(\text{CH}_2^t\text{Bu})_3(\text{THF})_2$  are formed by the reaction of

**Figure 1** Structure of  $[\text{Li}(\text{TMEDA})]_3[\text{ErMe}_6]$

ytterbium metal with  $\text{ICH}_2\text{SiMe}_3$  or neopentyl iodide in THF.<sup>12</sup> X-ray structural analyses of the  $\text{Sm}, \text{Er}, \text{Yb}$ , and  $\text{Lu}$  derivatives show the  $\text{Sm}$  atom in a *fac*-octahedral coordination and the heavier lanthanides  $\text{Er}, \text{Yb}$ , and  $\text{Lu}$  trigonal bipyramidally coordinated with three alkyl ligands in equatorial and two THF molecules in axial positions (equation 2).<sup>13</sup> The tris(trimethylsilylmethyl)scandium and -yttrium derivatives are thermally unstable. The bulky  $\text{PhMe}_2\text{SiCH}_2$  ligand allows the isolation of thermally more robust analogues  $\text{Ln}(\text{CH}_2\text{SiMe}_2\text{Ph})_3(\text{THF})_2$  ( $\text{M} = \text{Sc}, \text{Y}$ ).<sup>14</sup> Reaction of  $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  ( $\text{Ln} = \text{Y}, \text{Lu}$ ) with  $\text{B}(\text{C}_6\text{X}_5)_3$  ( $\text{X} = \text{H}, \text{F}$ ) in the presence of crown ethers yields cationic lanthanide-alkyl complexes, for example,  $[\text{Ln}(\text{CH}_2\text{SiMe}_3)_2(\text{CE})(\text{THF})_n]^+ [\text{B}(\text{CH}_2\text{SiMe}_3)(\text{C}_6\text{X}_5)_3]^-$  ( $\text{CE} = 12\text{-crown-4}, n = 1$ ;  $\text{CE} = 15\text{-crown-5}$  and  $18\text{-crown-6}, n = 0$ ) (equation 3).<sup>15</sup> The use of four equivalents of  $\text{LiCH}_2\text{SiMe}_3$  results in the formation of *ate* complexes  $[\text{Li}(\text{TMEDA})_2][\text{Ln}(\text{CH}_2\text{SiMe}_3)_4]$  ( $\text{Ln} = \text{Y}, \text{Er}, \text{Yb}$ ). Similar homoleptic tetrakis-alkyl anions are formed when  $\text{YCl}_3$  reacted with 2 equiv. of  $\text{LiCH}_2\text{SiMe}_3$  and 2 equiv. of  $\text{LiOCMe}_3$  to yield  $\{(\text{Me}_3\text{SiCH}_2)_x(\text{Me}_3\text{CO})_{1-x}\text{Y}(\mu\text{-OCMe}_3)_4[\text{Li}(\text{THF})_4(\mu_4\text{-Cl})]^+ [\text{Y}(\text{CH}_2\text{SiMe}_3)_4]^-$ .<sup>11</sup>

A number of analogous bis(trimethylsilyl)methyl lanthanide complexes have also been reported.  $[(\text{Et}_2\text{O})_3\text{Li}(\mu\text{-Cl})\text{Y}[\text{CH}(\text{SiMe}_3)_2]_3]$  and the solvent-free  $\text{Y}[\text{CH}(\text{SiMe}_3)_2]_3$  have been prepared and structurally characterized recently.<sup>3,11</sup>

Mixed lanthanide metal(III) alkyl complexes  $\text{R}_3\text{Ln}(\mu\text{-Me})\text{Li}(\text{pmdeta})$  [ $\text{Ln} = \text{La}, \text{Sm}$ ;  $\text{R} = \text{CH}(\text{SiMe}_3)_2$ ;  $\text{pmdeta} = \text{MeN}(\text{CH}_2\text{CH}_2\text{NMe}_2)_2$ ] were prepared from  $\text{LnR}_3$ ,  $\text{LiMe}$ , and  $\text{pmdeta}$ . The reaction of  $\text{YbCl}_3$  with 3-(dimethylamino)propyllithium in THF affords the *ate* complex  $\text{Li}[(\text{Me}_2\text{NCH}_2\text{CH}_2\text{CH}_2)_4\text{Yb}]$ , in which two  $\text{Me}_2\text{N}$  groups intramolecularly chelate the  $\text{Yb}$  atom whereas the other two donor functions are coordinated to lithium.

Homoleptic aryl-lanthanides are less studied than alkyl complexes. After the first lanthanide aryl complex  $[\text{Li}(\text{THF})_4][\text{Lu}(\text{C}_6\text{H}_3\text{-2,6-Me}_2)_4]$ , neutral triphenyllanthanides  $\text{Ph}_3\text{Ln}(\text{THF})_3$  ( $\text{Ln} = \text{Er}, \text{Tm}, \text{Yb}$ ) were synthesized in THF by reaction of metallic lanthanides with  $\text{Ph}_2\text{Hg}$  or

$\text{Ph}_3\text{Bi}$  in the presence of catalytic amounts of  $\text{LnI}_2$  or  $\text{LnI}_3$ . X-ray diffraction studies showed that these compounds represent monomeric complexes with a distorted *fac*-octahedral arrangement of ligands around the Ln atom. Transmetalation of  $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{THF})_2$  with  $\text{Ph}_2\text{Hg}$  or  $\text{Ph}_3\text{Bi}$  in THF affords  $\text{Ph}_2(\text{THF})\text{Yb}(\mu\text{-Ph})_3\text{Yb}(\text{THF})_3$  (equation 4)

The X-ray crystal structure analysis of  $\text{Ph}_3\text{Sc}(\text{THF})_2$  reveals a trigonal-bipyramidal coordination sphere with the THF molecules in axial positions. The 1:1 or 2:1 reactions of  $\text{Li}[\text{C}_6\text{H}_3\text{-2,6-(O}^i\text{Pr)}_2]$  with anhydrous  $\text{SmCl}_3$  in THF gave  $[2,6\text{-}(^i\text{PrO})_2\text{C}_6\text{H}_3]_3\text{Sm}$  exclusively, while the 3:1 reaction gave  $[2,6\text{-}(^i\text{PrO})_2\text{C}_6\text{H}_3]_4\text{SmLi}$  as the major product, which has been characterized by X-ray crystallography.<sup>11</sup>

## 2.2 Complexes with Two $\eta^1$ -Bonded Hydrocarbyls

Dibenzylttrium bromides like  $[(\text{TMEDA})(\text{PhCH}_2)_2\text{-Y}(\mu\text{-Br})_2\text{Li}(\text{TMEDA})]$  are formed from  $\text{YBr}_3$  and  $\text{PhCH}_2\text{Li}(\text{TMEDA})$ .<sup>11</sup> Different ancillary ligands provide stabilization of bis(alkyl)lanthanide derivatives such as described earlier in  $\text{Cp}_2\text{Lu}(\mu\text{-Me})_2\text{Li}(\text{TMEDA})$ ,  $[\text{Cp}^*_2\text{-Lu}(\text{CH}_2\text{SiMe}_3)_2][\text{Li}(\text{DME})_2]$ , and  $[\text{Cp}_2\text{Y}(\text{CH}_2\text{SiMe}_3)_2]_2\text{-Li}_2(\text{DME})_2(\text{dioxane})$ .<sup>6</sup> The reactions of  $\text{ScCl}_3$  and  $\text{LuCl}_3$  with one equiv. of  $\text{K}[(S)\text{-C}_5\text{H}_4\text{CHPhCH}_2\text{NMe}_2]$  or  $\text{K}[\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{NMe}_2]$  followed by two equiv. of  $\text{LiCH}_2\text{-SiMe}_3$  yield the complexes  $[(S)\text{-C}_5\text{H}_4\text{CHPhCH}_2\text{NMe}_2]\text{-Ln}(\text{CH}_2\text{SiMe}_3)_2$  (equation 5) and  $(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{-Ln}(\text{CH}_2\text{SiMe}_3)_2$  (equation 6), respectively.<sup>16</sup>

$\text{SmBr}_3$  and  $\text{GdBr}_3$  react with  $\text{NaCH}_2\text{Ph}$  and  $\text{KCp}^*$  in THF to give  $[\text{Cp}^*_2\text{Sm}(\text{CH}_2\text{Ph})_2\text{K}(\text{THF})_2]_\infty$  and  $\text{Cp}^*\text{Gd}(\text{CH}_2\text{Ph})_2(\text{THF})$ , respectively.<sup>11</sup> Rare earth metal complexes of the type  $\text{Ln}\{\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2(\text{C}_4\text{H}_3\text{O-2})\}(\text{CH}_2\text{SiMe}_3)_2(\text{THF})$  ( $\text{Ln} = \text{Y, Lu}$ ) (Figure 2a) were prepared by alkane elimination reaction of  $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  with the 2-furyl-functionalized tetramethylcyclopentadiene. Reaction of these dialkyl complexes with  $\text{BPh}_3$  in THF give thermally stable cations  $[\text{Ln}\{\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2(\text{C}_4\text{H}_3\text{O-2})\}(\text{CH}_2\text{SiMe}_3)(\text{THF})_n]^+$ .<sup>17</sup> The in situ generated  $\text{Sc}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  reacts with the protonated hydrotris-pyrazolylborate ligands (see *Tris(pyrazolyl)borates*)  $\text{Tp}^{\text{Me,Me,H}}$  and  $\text{Tp}^{\text{tBu,Me,H}}$  affording  $(\text{Tp}^{\text{Me,Me}})\text{Sc}(\text{CH}_2\text{SiMe}_3)_2$  and  $(\text{Tp}^{\text{tBu,Me}})\text{Sc}(\text{CH}_2\text{SiMe}_3)_2$  (Figure 2b), respectively. Treatment of  $(\text{Cp}_2\text{YCl})_2$  with two equiv. of 2-dimethylaminomethylferrocenyl lithium  $\text{Li}(\text{FcN})$  affords the heterotrimetallic complex  $\text{Li}[\text{Cp}_2\text{Y}(\text{FcN})_2]$  (Figure 2c).<sup>6,11</sup>

**Figure 2** (a)  $\text{Ln}\{\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2(\text{C}_4\text{H}_3\text{O-2})\}(\text{CH}_2\text{SiMe}_3)_2\text{-}(\text{THF})$  ( $\text{Ln} = \text{Y, Lu}$ ), (b)  $(\text{Tp}^{\text{tBu,Me}})\text{Sc}(\text{CH}_2\text{SiMe}_3)_2$ , and (c)  $\text{Li}[\text{Cp}_2\text{-Y}(\text{FcN})_2]$

Addition of  $\text{RLi}$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ , and  $\text{CH}_2\text{SiMe}_3$ ) to  $\text{ScCl}_2(\text{THF})[\text{N}(\text{SiMe}_2\text{CH}_2\text{P}^i\text{Pr}_2)_2]$  gives bis-alkyl derivatives  $\text{R}_2\text{Sc}[\text{N}(\text{SiMe}_2\text{CH}_2\text{P}^i\text{Pr}_2)_2]$ . The X-ray structural analysis of  $\text{Et}_2\text{Sc}[\text{N}(\text{SiMe}_2\text{CH}_2\text{P}^i\text{Pr}_2)_2]$  and  $(\text{Me}_3\text{SiCH}_2)_2\text{Sc}[\text{N}(\text{SiMe}_2\text{CH}_2\text{P}^i\text{Pr}_2)_2]$  show mononuclear molecules with distorted trigonal-bipyramidal geometries.<sup>11</sup> The alkane elimination reaction between  $\text{Y}(\text{CH}_2\text{SiMe}_2\text{Ph})_3(\text{THF})_2$  and 1 equiv. of salicylaldimine (LH) results in the formation of the dialkyl derivatives  $\text{LY}(\text{CH}_2\text{SiMe}_2\text{Ph})_2(\text{THF})$  (Figure 3a).<sup>14</sup> Bis-alkyl derivatives  $(\text{L}')\text{Ln}(\text{CH}_2\text{SiMe}_3)_2(\text{THF})$  ( $\text{Ln} = \text{Sc}$  or  $\text{Y}$ ) were obtained by the reaction of equimolar amounts of the related salicylaldimine ligand 2-(2,4,6- $\text{Me}_3\text{C}_6\text{H}_2\text{N}=\text{CH}$ )-(6- $^t\text{Bu}$ ) $\text{C}_6\text{H}_3\text{OH}$  ( $\text{L}'\text{H}$ ) with  $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_3$ . The trigonal-bipyramidal structure of the scandium dialkyl complex was confirmed crystallographically.<sup>11</sup> The scandium alkyl complexes are efficient catalysts for the ring-opening polymerization of  $\epsilon$ -caprolactone.<sup>18</sup> The  $\beta$ -diketiminate complex  $(\text{L})_2\text{CeCl}$  [ $\text{L} = \text{N}(\text{R})\text{C}(\text{Ph})\text{C}(\text{H})\text{C}(\text{Ph})\text{NR}$ ;  $\text{R} = \text{SiMe}_3$ ] reacts with either one or two equiv. of  $\text{Li}(\text{CHR}_2)$  in  $\text{Et}_2\text{O}$ , forming  $(\text{L})\text{Ce}[\text{CH}(\text{SiMe}_3)_2]_2$  (Figure 3b).<sup>11</sup>

Several diorganoscandium complexes stabilized by the  $\beta$ -diketiminate ligands  $(\text{Ar})\text{NC}(\text{R})\text{CHC}(\text{R})\text{N}(\text{Ar})$  ( $\text{L}'$ :  $\text{Ar} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$ ,  $\text{R} = \text{CH}_3$ ;  $\text{L}''$ :  $\text{Ar} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$ ,  $\text{R} = ^t\text{Bu}$ ) have been reported. Thus, reactions of the lithium salts of the ligands  $\text{L}'$  and  $\text{L}''$  with  $\text{ScCl}_3(\text{THF})_3$  lead to the complexes  $(\text{L}')\text{ScCl}_2(\text{THF})_n$  and  $(\text{L}'')\text{ScCl}_2(\text{THF})_n$ , which are readily alkylated with various organolithium compounds or Grignard

reagents to form the dialkyl derivatives  $(\text{L}')\text{ScR}_2$  ( $\text{R} = \text{PhCH}_2$ ,  $^t\text{BuCH}_2$  and  $\text{Me}_3\text{SiCH}_2$ ) and  $(\text{L}'')\text{ScR}_2$  ( $\text{R} = \text{CH}_3$ ,  $\text{CH}_3\text{CH}_2$ ,  $\text{PhCH}_2$ ,  $^t\text{BuCH}_2$  and  $\text{Me}_3\text{SiCH}_2$ ). Most of them are isolated as base-free, four-coordinate complexes and characterized via X-ray crystallography. Steric interactions between  $\text{Ar}$  and the  $\text{Sc}$ -alkyl groups force the scandium to adopt an out-of-plane bonding mode.<sup>19</sup> The reaction of  $(\text{L}')\text{ScMe}_2$  with 1 equiv. of  $\text{B}(\text{C}_6\text{F}_5)_3$  yields monomeric monomethyl cations  $[(\text{L})\text{ScMe}]^+[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$ .<sup>20</sup> The reaction of  $[(\text{L})\text{LuCl}_2(\mu\text{-Cl})(\mu\text{-Li}(\text{THF})_2)]_2$  [ $\text{L} = 2,6\text{-(Me}_2\text{NCH}_2)_2\text{C}_6\text{H}_3$ ] with  $\text{Me}_3\text{SiCH}_2\text{Li}$  gives the monoalkyl complex  $[(\text{L})\text{Lu}(\mu\text{-Cl})(\text{CH}_2\text{SiMe}_3)]_2$ , which reacts with a second equiv. of  $\text{Me}_3\text{SiCH}_2\text{Li}$  to produce the bis-alkyl complex  $(\text{L})\text{Lu}(\text{CH}_2\text{SiMe}_3)_2$  (Figure 4a).<sup>11</sup>  $\text{YCl}_3$  reacts with the lithium salt of an anilido-imine ligand and 2 equiv. of  $\text{LiCH}_2\text{SiMe}_2\text{R}$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ) yielding monomeric bis(alkyl)yttrium complexes  $(\text{L})\text{Y}(\text{CH}_2\text{SiMe}_2\text{R})_2$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ) (Figure 4b).<sup>21</sup>

The sequential reaction of  $\text{YCl}_3$  with  $\text{Li}[^t\text{BuC}(\text{N}^i\text{Pr})_2]$  and 2 equiv. of  $\text{LiCH}(\text{SiMe}_3)_2$  form the mono(amidinate) dialkyl yttrium complex  $[^t\text{BuC}(\text{N}^i\text{Pr})_2]\text{Y}[\text{CH}(\text{SiMe}_3)_2]_2(\mu\text{-Cl})\text{Li}(\text{THF})_3$ . Using the tridentate amidinate-amine ligand  $\text{PhC}(\text{NSiMe}_3)\text{N}(\text{CH}_2)_2\text{NMe}_2$  ( $\text{L}$ ) results in the formation of the salt-free dialkyl complex  $(\text{L})\text{Y}[\text{CH}(\text{SiMe}_3)_2]_2$  (Figure 5a). Attempts to prepare analogous benzyl or  $\text{CH}_2\text{SiMe}_3$  complexes yielded the *ate* complexes  $\text{Li}[(\text{L})_2\text{YR}_2]$  ( $\text{R} = \text{CH}_2\text{Ph}$ ,  $\text{CH}_2\text{SiMe}_3$ ).<sup>22</sup> The reaction between aza-18-crown-6 ( $\text{H-MAC}$ ) and  $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  proceeded via elimination of  $\text{SiMe}_4$ , yielding  $\text{Y}(\text{MAC})(\text{CH}_2\text{SiMe}_3)_2$  (Figure 5b).<sup>11</sup> Yttrium dialkyl complexes supported by tetradentate ligands [ $\text{N},\text{N}'\text{-R}_2\text{-tacn-N''-(CH}_2)_2\text{N}^t\text{Bu}$ ] ( $\text{R} = \text{Me}$ ,  $\text{tacn} = 1,4,7\text{-triazacyclononane}$ ) have been prepared analogously using  $\text{H-tacn}$  (Figure 5c).<sup>23</sup>

Mixed dialkyl-alkoxide complexes are also known, for example,  $(\text{Me}_3\text{SiCH}_2)\text{Sm}[(\mu\text{-OAr})(\mu\text{-CH}_2\text{SiMe}_3)\text{Li}(\text{THF})][(\mu\text{-OAr})_2\text{Li}(\text{THF})]$  ( $\text{Ar} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$ ), containing a pentacoordinate  $\text{Sm}$  center ligated by one terminal and one bridging  $\text{CH}_2\text{SiMe}_3$  and three bridging 2,6- $^i\text{Pr}_2\text{C}_6\text{H}_3$  ligands. The anionic dialkyl-diaryloxide complex  $[(\text{Me}_3\text{SiCH}_2)_2\text{Lu}(\text{OC}_6\text{H}_3^t\text{Bu}_{2,6})_2][\text{Li}(\text{THF})_4](\text{THF})_2$  has a distorted tetrahedral coordination geometry around both

**Figure 3** (a)  $\text{LY}(\text{CH}_2\text{SiMe}_2\text{R})_2(\text{THF})_n$  and (b)  $(\text{L})\text{Ce}[\text{CH}(\text{SiMe}_3)_2]_2$

**Figure 4** (a)  $(\text{L})\text{Lu}(\text{CH}_2\text{SiMe}_3)_2$  and (b)  $(\text{L})\text{Y}(\text{CH}_2\text{SiMe}_2\text{R})_2$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ )

**Figure 5** (a)  $(\text{L})\text{Y}[\text{CH}(\text{SiMe}_3)_2]_2$ , (b)  $\text{Y}(\text{MAC})(\text{CH}_2\text{SiMe}_3)_2$ , and (c)  $[\text{tacn}]\text{Y}(\text{CH}_2\text{SiMe}_3)_2$

metals, whereas the related complex  $[(\text{Me}_3\text{Si})_2\text{CH}]_2\text{Y}(\mu\text{-O}^t\text{Bu})_2\text{Li}(\text{THF})$  has a distorted tetrahedral coordinated yttrium and a trigonal planar lithium. The reaction of  $\text{YCl}_3$  with 2 equiv. of  $\text{LiCH}_2\text{SiMe}_3$  and 1 equiv. of  $\text{LiOC}_6\text{H}_3^t\text{Bu}_{2,6}$  in THF forms the neutral dialkyl aryloxide complex  $(\text{Me}_3\text{SiCH}_2)_2\text{Y}(\text{OC}_6\text{H}_3^t\text{Bu}_{2,6})(\text{THF})_2$ . The coordination geometry around Y is distorted trigonal bipyramidal with the THF groups in the apical positions.<sup>11</sup>

### 2.3 Complexes with One $\eta^1$ -Bonded Hydrocarbyl Ligand

Organolanthanides of this class, especially dicyclopentadienyl derivatives  $\text{Cp}_2\text{LnR}$  are the most effective catalysts for olefin polymerization and they are selective and effective reagents for organic synthesis.<sup>9,24,25</sup> They were prepared by alkylation of  $\text{Cp}_2\text{LnCl}$  or by treatment of methylaluminates  $\text{Cp}_2\text{Ln}(\mu\text{-Me})_2\text{AlMe}_2$  with equimolar amounts of pyridine.<sup>6,25</sup> More recently  $[(\text{C}_5\text{H}_4\text{SiMe}_2\text{R})_2\text{Ln}(\mu\text{-Me})]_2$  ( $\text{R} = ^t\text{Bu}$ ,  $\text{Ln} = \text{Y}$ ,  $\text{Sm}$ ,  $\text{Lu}$ ;  $\text{R} = \text{Me}$ ,  $\text{Ln} = \text{Y}$ ,  $\text{Sm}$ ,  $\text{Lu}$ ),  $[\eta^5\text{-1,3-C}_5\text{H}_3(\text{SiMe}_3)_2]_2\text{LnMe}(\text{THF})$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Lu}$ ),<sup>26</sup>  $\{[1,3-(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_2\text{LnMe}\}_2$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Nd}$ ),<sup>27</sup> *rac*- $[\text{O}(\text{CH}_2\text{CH}_2\text{-C}_9\text{H}_6)_2]_2\text{LnCH}_2\text{SiMe}_3$  ( $\text{Ln} = \text{Y}$ ,  $\text{Lu}$ ),  $[\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\text{C}_5\text{H}_3\text{-CH}_2\text{CH}_2\text{NMe}_2)]_2\text{LnMe}$  ( $\text{Ln} = \text{Y}$ ,  $\text{Ho}$ ,  $\text{Lu}$ ) (Figure 6a),  $\text{Cp}^*(\text{C}_5\text{H}_3\text{CH}_2\text{CH}_2\text{NMe}_2)\text{ScMe}$  (Figure 6b),  $\text{Cp}^*(\text{C}_5\text{H}_3\text{CH}_2\text{CH}_2\text{NMe}_2)\text{LnMe}$  ( $\text{Ln} = \text{Nd}$ ,  $\text{Sm}$ ,  $\text{Ho}$ ,  $\text{Lu}$ ),  $\text{Cp}^*(\text{C}_5\text{H}_3\text{CH}_2\text{CH}_2\text{NMe}_2)\text{LuCH}_2\text{SiMe}_3$ ,  $(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{SEt})_2\text{YMe}$  (Figure 6c), and  $\text{Cp}^*(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{SEt})\text{LuMe}$ <sup>28</sup> have been described. Single-crystal X-ray structure analysis of the N- and S-donor functionalized complexes showed that donor

atoms are intramolecularly coordinated to the metal.  $\{[1,3-(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_2\text{LnMe}\}_2$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Nd}$ ) performs the living polymerization of methylmethacrylate and the block copolymerization of L-lactide with  $\epsilon$ -caprolactone in high yields in the absence of any cocatalysts.<sup>29</sup> Lanthanidocene methyl complexes are effective precatalysts for the hydrosilylation of alkenes and alkynes.<sup>24</sup>

Dimeric  $[(\text{C}_4\text{Me}_4\text{P})_2\text{LnCH}(\text{SiMe}_3)_2]_2$  ( $\text{Ln} = \text{Nd}$ ,  $\text{Sm}$ ) supported by the 2,3,4,5-tetramethylphospholyl ligand can be prepared in a one-pot procedure starting from  $\text{LnCl}_3$ ,  $\text{K}(\text{C}_4\text{Me}_4\text{P})$ , and  $\text{LiCH}(\text{SiMe}_3)_2$ . Reaction of  $(\text{C}_4\text{Me}_4\text{P})_2\text{LnCH}(\text{SiMe}_3)_2$  with  $\text{H}_2$  gives  $(\text{C}_4\text{Me}_4\text{P})_2\text{NdH}$  with  $\text{Ln} = \text{Nd}$ , in the case of  $\text{Ln} = \text{Sm}$ , reduction to  $(\text{C}_4\text{Me}_4\text{P})_2\text{Sm}$  takes place.<sup>11</sup>

$(\text{Me}_3\text{Si})_2\text{CH}$  derivatives can be prepared as monomeric alkali salt- and solvent-free complexes, like  $\text{Cp}^*_2\text{LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{La}$ ,  $\text{Nd}$ ,  $\text{Sm}$ ,  $\text{Lu}$ ),  $(\text{C}_5\text{Me}_4\text{Et})_2\text{LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Y}$ ,  $\text{Nd}$ ,  $\text{Sm}$ ),  $(\text{C}_5\text{Me}_4^i\text{Pr})_2\text{-LnCH}_3(\text{THF})$  ( $\text{Ln} = \text{Y}$ ,  $\text{Sm}$ ),  $(\text{C}_5\text{Me}_4^i\text{Pr})_2\text{Ln}\{\text{CH}(\text{SiMe}_3)_2\}$  ( $\text{Ln} = \text{Y}$ ,  $\text{Sm}$ ),  $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)_2\text{LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Y}$ ,  $\text{Nd}$ ),  $[\text{R}_2\text{Si}(\text{C}_5\text{H}_4)(\text{C}_5\text{Me}_4)]_2\text{LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Y}$ ,  $\text{Lu}$ ), and (*R*)- and (*S*)- $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\text{C}_5\text{H}_3\text{R}^*)\text{LnCH}(\text{SiMe}_3)_2$  [ $\text{Ln} = \text{Y}$ ,  $\text{Sm}$ ;  $\text{R}^* = (+)\text{-neomenthyl}$  or  $(-)\text{-menthyl}$ ]. However, alkylation of the bis(cyclopentadienyl)lanthanide halides with  $\text{MeLi}$  or  $\text{Me}_3\text{SiCH}_2\text{Li}$  often produces the *ate* complexes, for example,  $\text{Cp}_2\text{Ln}(\mu\text{-Me})_2\text{Li}(\text{TMEDA})$ ,  $\text{Cp}^*_2\text{Ln}(\mu\text{-Me})_2\text{Li}(\text{THF})_2$ ,  $\text{Cp}^*_2\text{Ln}(\mu\text{-Me})_2\text{Li}(\text{THF})_2$ ,  $\text{Cp}^*_2\text{Ln}(\mu\text{-CH}_2\text{SiMe}_3)_2\text{Li}(\text{DME})_2$ , and  $(\text{C}_5\text{H}_4\text{SiMe}_3)_2\text{Ln}(\mu\text{-Me})_2\text{Li}(\text{THF})_2$ .<sup>8</sup>

Compounds  $\text{Cp}^*_2\text{LnCH}(\text{SiMe}_3)_2$  can be converted to the highly reactive hydrides  $(\text{Cp}^*_2\text{LnH})_2$  by reaction with

**Figure 6** (a)  $[\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\text{C}_5\text{H}_3\text{CH}_2\text{CH}_2\text{NMe}_2)]_2\text{LnMe}$ , (b)  $\text{Cp}^*(\text{C}_5\text{H}_3\text{CH}_2\text{CH}_2\text{NMe}_2)\text{ScMe}$ , (c)  $(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{SEt})_2\text{YMe}$

hydrogen. For instance,  $(\text{Cp}^*\text{YH})_2$  metalates pyridine selectively in *ortho*-position to yield  $\text{Cp}^*\text{Y}(\text{2-pyridyl})$ , which further reacts with ethylene or propylene to give the monoinsertion products  $\text{Cp}^*\text{YCH}_2\text{CH}_2(\text{2-NC}_5\text{H}_4)$  and  $\text{Cp}^*\text{YCH}_2\text{CHMe}(\text{2-NC}_5\text{H}_4)$ , respectively. With 2-butyne, the propargylic metallation product  $\text{Cp}^*\text{YCH}_2\text{C}\equiv\text{CMe}$  was obtained.

$[\text{Me}_2\text{Si}(\text{N}^t\text{Bu})(\text{O}^t\text{Bu})]_2\text{YCH}(\text{SiMe}_3)_2$  reacts with  $\text{N}\equiv\text{CMe}$  via C–H activation forming  $[\{\text{Me}_2\text{Si}(\text{N}^t\text{Bu})(\text{O}^t\text{Bu})\}_2\text{Y}(\mu\text{-(N,N')-NHCMe=CHCN})]_2$  (equation 7). With pyridine and picoline, the metallation of either cyclic or exocyclic positions yields pyridyl and picolyl complexes,  $[\text{Me}_2\text{Si}(\text{N}^t\text{Bu})(\text{O}^t\text{Bu})]_2\text{YR}$  ( $\text{R} = \eta^2\text{-(C}_5\text{N)-2-NC}_5\text{H}_4$ ,  $\eta^2\text{-(C}_5\text{N)-CH}_2\text{-2-NC}_5\text{H}_4$ ,  $\eta^2\text{-(C}_5\text{N)-C(H)Me-2-NC}_5\text{H}_4$ ,  $\eta^2\text{-(C}_5\text{N)-C(H)Me-2-NC}_5\text{H}_3\text{-6-Me}$ ), respectively.

The reaction of the half-sandwich complex (*see Half-sandwich Complexes*)  $(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})$  with furan and thiophene yields  $[(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})\text{Y}(\mu_2\text{-C}_4\text{H}_3\text{E})]_2$  ( $\text{E} = \text{O}, \text{S}$ ) (Figure 7). In contrast to THF and pyridine, DME forms isolable, crystalline adducts  $(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})\text{Y}(\text{2-C}_4\text{H}_3\text{E})(\text{DME})$ . The reaction of  $[\text{Y}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\text{CH}_2\text{SiMe}_3)(\text{THF})]$  with excess DME yields the five-coordinate complex  $[\text{Y}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\text{CH}_2\text{SiMe}_3)(\text{DME})]$  that does not react with furan or thiophene, indicating an associative mechanism.<sup>30</sup>

Figure 7  $[(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})\text{Y}(\mu_2\text{-C}_4\text{H}_3\text{E})]_2$  ( $\text{E} = \text{O}, \text{S}$ )

The dimeric rare earth hydrides based on the same Cp/amide 'constrained geometry' ligand  $[\text{Ln}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\text{THF})(\mu\text{-H})]_2$  ( $\text{Ln} = \text{Y}, \text{Yb}$ ) react with an excess of  $\alpha$ -olefins  $\text{H}_2\text{C}=\text{CHR}$  ( $\text{R} = \text{Et}, ^n\text{Pr}, ^n\text{Bu}$ ) in a 1,2-insertion manner to give the series of THF-free dimeric *n*-alkyl complexes  $[\text{Ln}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\mu\text{-CH}_2\text{CH}_2\text{R})]_2$ . Single-crystal X-ray diffraction studies on  $[\text{Y}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\mu\text{-CH}_2\text{CH}_2\text{R})]_2$  ( $\text{R}' = \text{Me}, \text{R} = \text{Et}, ^n\text{Bu}; \text{R}' = \text{Et}, \text{R} = \text{Et}, ^n\text{Pr}$ ) and  $[\text{Yb}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\mu\text{-CH}_2\text{CH}_2^n\text{Bu})]_2$  revealed that the centrosymmetric dimeric complexes consist of two trans arranged  $[\text{Ln}(\eta^5\text{:}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N}^t\text{Bu})(\mu\text{-CH}_2\text{CH}_2\text{R})]$  fragments connected by two  $\mu$ -alkyl ligands, showing an agostic interaction (*see Agostic Bonding*) of the  $\beta$ -CH<sub>2</sub> hydrogen atoms of the *n*-alkyl groups with the formally 12-electron lanthanide metal center.  $\alpha$ -Olefins having two or more substituents on the  $\gamma$ -carbon do not react with the hydride complexes.<sup>31</sup> The scandium complex  $[\text{C}_5\text{H}_3(1\text{-SiMe}_2\text{N}^t\text{Bu})(3\text{-CH}_2\text{CH}_2\text{NMe}_2)]\text{Sc}(\text{CH}_2\text{SiMe}_3)$  was prepared via alkane elimination by treatment of in situ generated  $\text{Sc}(\text{CH}_2\text{SiMe}_3)_3$  with the free ligand.

A number of chelating polydentate N-based ligands are useful to stabilize monoalkyl lanthanide complexes. The synthetic approach is alkane elimination from tris(alkyl)lanthanide precursors by treatment with protonated N-ligands. Deprotonation of *N,N*-dihydro-4,13-diaza-18-crown-6 ( $\text{H}_2\text{DAC}$ ) with  $\text{Y}(\text{CH}_2\text{SiMe}_3)_3$  yields the salt-free monoalkyl derivative  $(\text{DAC})\text{Y}(\text{CH}_2\text{SiMe}_3)$  (Figure 8), which is related to  $(\text{MAC})\text{Y}(\text{CH}_2\text{SiMe}_3)_2$  (Figure 5b).<sup>11</sup>

The reaction of  $(\text{DAC})\text{Y}(\text{CH}_2\text{SiMe}_3)$  with  $\text{PhC}\equiv\text{CH}$  produces a mixture of the alkynide-coupled butatrienediyl complex  $[(\mu\text{-DAC})\text{Y}]_2(\mu\text{-Z})\text{-PhC}\equiv\text{C}=\text{C}=\text{CPh}$  and the uncoupled bridging alkynide dimer  $[(\text{DAC})\text{Y}(\mu\text{-C}\equiv\text{CPh})]_2$ . Reaction of  $\text{Lu}[\text{CH}(\text{SiMe}_3)_2]_3$  with octaethylporphyrin ( $\text{H}_2\text{OEP}$ ) affords  $(\text{OEP})\text{Lu}[\text{CH}(\text{SiMe}_3)_2]$ . Its crystal structure showed a highly bowl-shaped porphyrin skeleton with the square-pyramidal, five-coordinate lutetium atom 0.918 Å out of the  $\text{N}_4$  plane of the porphyrin ligand. Monoalkyl diamide complexes  $(\text{BDPPpyr})\text{Ln}(\text{CH}_2\text{SiMe}_3)(\text{THF})_n$  ( $n = 1, \text{Ln} = \text{Sc}$  (Figure 9a),  $\text{Lu}$ ;  $n = 2, \text{Ln} = \text{Y}$ ),  $(\text{BMespyr})\text{Ln}(\text{CH}_2\text{SiMe}_3)(\text{THF})_n$  ( $n = 1, \text{Ln} = \text{Sc}$ ;  $n = 2, \text{Ln} = \text{Lu}$ ), and  $(\text{BDPPoxyl})\text{Ln}(\text{CH}_2\text{SiMe}_3)(\text{THF})$  ( $\text{Ln} = \text{Sc}$  (Figure 9b),  $\text{Lu}, \text{Y}$ ) were prepared from 2,6-bis[[(2,6-diisopropylphenyl)amino]methyl]pyridine ( $\text{H}_2\text{BDPPpyr}$ ), 2,6-bis[(mesitylamino)methyl]pyridine ( $\text{H}_2\text{BMespyr}$ ), or 1,2-bis[[(2,6-diisopropylphenyl)amino]methyl]benzene ( $\text{H}_2\text{BDPPoxyl}$ ) respectively using  $\text{Ln}(\text{CH}_2\text{SiMe}_3)_3$ .<sup>32</sup>

Figure 8  $(\text{DAC})\text{Y}(\text{CH}_2\text{SiMe}_3)$

**Figure 9** (a) (BDPPpyr)Sc(CH<sub>2</sub>SiMe<sub>3</sub>)(THF)<sub>n</sub> and (b) (BDPPoxyl)Sc(CH<sub>2</sub>SiMe<sub>3</sub>)(THF)

[ArN(CH<sub>2</sub>)<sub>3</sub>NAr]Y[CH(SiMe<sub>3</sub>)<sub>2</sub>](THF) (Ar = 2,6-*i*-Pr<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) is formed by alkali metal–salt elimination. The ‘ate-complex’ is not formed because of the low solubility of KI and its complete precipitation.<sup>33</sup> Yttrium bis(silylamido)biphenyl complexes [DADMB]YMe(THF)<sub>2</sub> and [DADMB]Y[CH(SiMe<sub>3</sub>)<sub>2</sub>](THF)(OEt<sub>2</sub>) (DADMB = 2, 2′-bis[(*tert*-butyldimethylsilyl)amido]-6,6′-dimethylbiphenyl) result from the reaction of [DADMB]YCl(THF)<sub>2</sub> and MeLi or (Me<sub>3</sub>Si)<sub>2</sub>CHLi, respectively. Both compounds react with PhSiH<sub>3</sub> or H<sub>2</sub> to give insoluble {[DADMB]Y(μ-H)(THF)}<sub>2</sub>, which reacts rapidly with ethene or 1-hexene to give a single insertion product.<sup>11</sup>

Amidinate ligands stabilize monoalkyl lanthanide derivatives like [PhC(NSiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>YCH(SiMe<sub>3</sub>)<sub>2</sub>, [PhC(NSiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>Y(μ-Me)<sub>2</sub>Li(TMEDA), [*p*-MeOC<sub>6</sub>H<sub>4</sub>C(NSiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>YCH(SiMe<sub>3</sub>)<sub>2</sub>, [(Me<sub>3</sub>Si)<sub>2</sub>NC(N<sup>*i*</sup>Pr)<sub>2</sub>]<sub>2</sub>YCH(SiMe<sub>3</sub>)<sub>2</sub>, [(Me<sub>3</sub>Si)<sub>2</sub>NC(N<sup>*i*</sup>Pr)<sub>2</sub>]<sub>2</sub>Y(μ-Me)<sub>2</sub>Li(TMEDA), [(Me<sub>3</sub>Si)<sub>2</sub>NC(N<sup>*i*</sup>Pr)<sub>2</sub>]<sub>2</sub>Y-(<sup>*t*</sup>Bu),<sup>34</sup> [Me<sub>3</sub>SiNC(Ph)N(CH<sub>2</sub>)<sub>3</sub>NC(Ph)NSiMe<sub>3</sub>]<sub>2</sub>Y[CH(SiMe<sub>3</sub>)<sub>2</sub>](THF),<sup>35</sup> {CyNC[N(SiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>NCy}<sub>2</sub>LnCH(SiMe<sub>3</sub>)<sub>2</sub> (Ln = Sm, Yb), [(Me<sub>3</sub>Si)<sub>2</sub>NC(N<sup>*i*</sup>Pr)<sub>2</sub>]<sub>2</sub>Ln(μ-Me)<sub>2</sub>Li(TMEDA) (Ln = Yb, Nd (Figure 10)),<sup>36</sup> [PhC(NSiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>-ScR (R = CH<sub>2</sub>SiMe<sub>3</sub>, Mes), and [PhC(NSiMe<sub>3</sub>)<sub>2</sub>]<sub>2</sub>ScMe(THF).

In THF, deprotonation of Ln[N(SiMe<sub>3</sub>)<sub>2</sub>]<sub>3</sub> (Ln = Sc, Yb, Lu) with NaN(SiMe<sub>3</sub>)<sub>2</sub> leads to complexes

**Figure 10** [(Me<sub>3</sub>Si)<sub>2</sub>NC(N<sup>*i*</sup>Pr)<sub>2</sub>]<sub>2</sub>Nd(μ-Me)<sub>2</sub>Li(TMEDA)

**Figure 11** (a) [(Me<sub>3</sub>Si)<sub>2</sub>N]<sub>2</sub>LnN(SiMe<sub>3</sub>)SiMe<sub>2</sub>CH<sub>2</sub>Na(THF)<sub>3</sub> and (b) (Et<sub>8</sub>-calix-pyrrole)(R)Sm(μ<sub>3</sub>-Cl)[Li(THF)<sub>2</sub>][Li(THF)<sub>2</sub>] (R = Me, CH=CH<sub>2</sub>)

containing a planar four-membered LnCSiN ring system with a linear Ln–C–Na arrangement (Figure 11a). Methyl- and vinyl-substituted Sm derivatives supported by a calix-tetrapyrrole ligand (Et<sub>8</sub>-calix-pyrrole)(R)Sm(μ<sub>3</sub>-Cl)[Li(THF)<sub>2</sub>][Li(THF)<sub>2</sub>] (R = Me, CH=CH<sub>2</sub>) (Figure 11b) were prepared by the reaction of (Et<sub>8</sub>-calix-pyrrole)(Cl)Sm-[Li<sub>2</sub>(THF)<sub>3</sub>] with the corresponding organolithium reagents. The methyl derivative reacts with hydrogen affording the corresponding samarium hydride (Et<sub>8</sub>-calix-pyrrole)(THF)Sm-[Li(THF)<sub>2</sub>](μ<sub>3</sub>-H).<sup>37</sup>

Monoalkyl complexes, (L)LnCH<sub>2</sub>SiMe<sub>3</sub> (L = 1,3-di[2-(*N*-isopropylamino)troponimine]propane, Ln = La, Lu) (Figure 12a)<sup>38</sup> and a scandium alkyl complex bearing a diamide–diamine donor ligand (Figure 12b) are also known.<sup>39,40</sup>

The neutral monobenzyl compound Cp\*<sub>2</sub>Y(CH<sub>2</sub>Ph)(THF) was obtained by the reaction of YBr<sub>3</sub> with benzylpotassium and KCp\* in THF.<sup>11</sup> Terphenyl complexes (Dmp)LnCl<sub>2</sub>(THF)<sub>n</sub> [Dmp = 2,6-di(mesityl)phenyl; Ln = Sc,

**Figure 12** (a) (*i*PrNC<sub>8</sub>H<sub>6</sub>NCH<sub>2</sub>CH<sub>2</sub>NC<sub>8</sub>H<sub>6</sub>N<sup>*i*</sup>Pr)LnCH<sub>2</sub>SiMe<sub>3</sub> and (b) [N(CH<sub>2</sub>CH<sub>2</sub>NSiMe<sub>3</sub>)CH<sub>2</sub>C<sub>5</sub>H<sub>4</sub>N]ScCH<sub>2</sub>SiMe<sub>3</sub>

Yb,  $n = 2$ ; Ln = Y,  $n = 3$ ] and  $(\text{Dnp})\text{LnCl}_2(\text{THF})_2$  [Dnp = 2,6-di(1-naphthyl)phenyl, Ln = Yb, Tm, Y] were prepared in THF from  $\text{LnCl}_3$ , and  $(\text{Dmp})\text{Li}$  and  $(\text{Dnp})\text{Li}$ , respectively. The Dnp complexes are monomeric with distorted trigonal-bipyramidal (Sc and Yb) or octahedral (Y) coordination geometry about the metal atom, with the two Cl atoms occupying the axial positions.<sup>41</sup> Complexes  $(\text{Dnp})\text{LnCl}_2(\text{THF})_2$  (Ln = Yb, Tm, Y) exhibit distorted trigonal-bipyramidal coordination environments at the metal center, with the two O atoms of the THF ligands occupying the axial positions of a trigonal-bipyramidal coordination polyhedron.<sup>42</sup> The complexes with donor-functionalized terphenyl ligands  $[(\text{Danip})\text{Yb}(\mu\text{-Cl})_2(\mu_3\text{-Cl})\text{Li}(\text{THF})]_2$  and  $[(\text{Danip})\text{Ln}(\mu_2\text{-Cl})_2(\mu_2\text{-Cl})\text{Li}(\text{THF})_2]_2$  (Ln = Y, Sm; Danip = 2,6-di(*o*-anisyl)phenyl) are obtained from the reaction of equimolar amounts of  $(\text{Danip})\text{Li}$  and  $\text{LnCl}_3$  (Ln = Yb, Y, Sm) in THF. These complexes are dimeric and composed of lithium chloride-bridged  $(\text{Danip})\text{LnCl}_2$  moieties, stabilized through additional coordination of two methoxy functions to the lanthanide atom.<sup>43</sup> The structurally characterized lanthanidocene terphenyl derivatives  $(\text{C}_5\text{H}_4\text{Me})_2\text{YbR}$  and  $\text{Cp}_2\text{SmR}$  [R = 2,6-(2,4,6-Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>] were obtained by the reaction of  $\text{RLi}$  with  $(\text{C}_5\text{H}_4\text{Me})_3\text{Yb}$  or  $\text{Cp}_3\text{Sm}$  in toluene.<sup>11</sup>

$\text{Cp}^*_2\text{SmPh}(\text{THF})$  is available by transmetalation between  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  and  $\text{Ph}_2\text{Hg}$ . The solvent-free complex  $[\text{Cp}^*_2\text{SmPh}]_2$  thermally decomposes to yield benzene and the phenylene-bridged disamarium complex  $\text{Cp}^*_2\text{Sm}(\mu\text{-1,4-C}_6\text{H}_4)\text{SmCp}^*_2$ .<sup>44</sup>  $\text{SmBr}_3$  reacts with  $\text{Li}^+{}_2(\text{biph})^{2-}$  in THF to form dimeric  $[(\text{quaph})\text{SmBr}(\text{THF})_2]_2$  (quaph = *o*-quaterphenyl) in which both Sm atoms are coordinated by a quaph ligand each and two THF molecules besides two bridging Br atoms resulting in a distorted octahedral coordination of the Sm atoms (Figure 13).<sup>12</sup>

$\text{Cp}_3\text{La}(\text{THF})$  reacts with  $\text{Li}[\text{C}_6\text{H}_3(\text{CH}_2\text{NMe}_2)_2\text{-2,6}]$  yielding  $\text{Cp}_2\text{La}[\text{C}_6\text{H}_3(\text{CH}_2\text{NMe}_2)_2\text{-2,6}]$  (Figure 14a); lanthanide complexes with the related mono-(Me<sub>2</sub>N)-substituted phenyl ligand,  $(\text{COT})\text{Ln}(\text{THF})(\text{C}_6\text{H}_4\text{CH}_2\text{NMe}_2\text{-2})$  (Ln = Er, Lu) and  $\text{Cp}_2\text{Y}(\text{C}_6\text{H}_4\text{CH}_2\text{NMe}_2\text{-2})$ , were prepared by alkylation of  $(\text{COT})\text{LnCl}(\text{THF})$  and  $\text{Cp}_2\text{YCl}$ , respectively, with  $\text{LiC}_6\text{H}_4\text{CH}_2\text{NMe}_2\text{-2}$ ; reactions of  $\text{LnCl}_3$  (M = Er, Yb, Lu) with 3 equiv. of  $\text{LiC}_6\text{H}_4\text{CH}_2\text{NMe}_2\text{-2}$  gave the homoleptic tris(aryl)lanthanides  $\text{Ln}(\text{C}_6\text{H}_4\text{CH}_2\text{NMe}_2\text{-2})_3$ ; and treatment of  $(\text{Cp}^*_2\text{SmH})_2$  with 2-phenyl-1-pyrroline causes

**Figure 14** (a)  $\text{Cp}_2\text{LaC}_6\text{H}_3(\text{CH}_2\text{NMe}_2)_2$  and (b)  $\text{Cp}^*_2\text{SmC}_6\text{H}_4\text{-C}_4\text{H}_6\text{N-2}$

orthometalation (*see Orthometalation*) resulting in the formation of  $\text{Cp}^*_2\text{SmC}_6\text{H}_4(2\text{-NC}_4\text{H}_6)$  (Figure 14b).

The first organolanthanide alkynide complexes  $[\text{Cp}_2\text{Ln}(\mu\text{-C}\equiv\text{C}'\text{Bu})]_2$  (Ln = Er, Yb) were synthesized by the halide-free reactions of  $[\text{Cp}_2\text{Ln}(\mu\text{-Me})]_2$  with  $\text{HC}\equiv\text{C}'\text{Bu}$ .<sup>6</sup> Alkynide bridged complexes  $[(\text{'BuCp})_2\text{Ln}(\mu\text{-C}\equiv\text{CPh})]_2$  (Ln = Nd, Gd) were prepared similarly. According to X-ray data for the Er, Nd, and Gd complexes, the two  $\text{Cp}_2\text{Ln}$  units of the dimers are connected by asymmetric alkynide bridges. Dimeric  $[(\text{MeC}_5\text{H}_4)_2\text{SmC}\equiv\text{C}'\text{Bu}]_2$  has been synthesized from  $(\text{MeC}_5\text{H}_4)_2\text{SmCl}$  and  $\text{LiC}\equiv\text{C}'\text{Bu}$  in THF. The early lanthanide alkyls  $\text{Cp}^*_2\text{LnCH}(\text{SiMe}_3)_2$  (Ln = Ce, La) react with terminal alkynes  $\text{HC}\equiv\text{CR}$  (R = Me,  $\text{'Bu}$ ) to produce oligomeric acetylides  $[\text{Cp}^*_2\text{LnC}\equiv\text{CR}]_n$  (Ln = Ce, R = Me,  $\text{'Bu}$ ; Ln = La, R = Me), which, in solution, rearrange to give the carbon-carbon coupled products,  $[\text{Cp}^*_2\text{Ln}]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-R}_2\text{C}_4)$  (Ln = Ce, R = Me,  $\text{'Bu}$ ; Ln = La, R = Me). The X-ray structures of  $[\text{Cp}^*_2\text{Ce}]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-R}_2\text{C}_4)$  (R = Me,  $\text{'Bu}$ ) show two  $\text{Cp}^*_2\text{Ce}$  units bridged by a conjugated  $\text{R}_2\text{C}_4$  group. The reaction of 2,4-dimethylpentadienylniodymium,  $(\text{C}_7\text{H}_{11})_3\text{Nd}$ , with  $\text{HC}\equiv\text{CPh}$  in toluene also leads to dimeric phenylethynyl derivatives  $[(\text{C}_7\text{H}_{11})_2\text{NdC}\equiv\text{CPh}]_2$ . The monomeric, solvent-free lanthanide alkynide tris(pyrazolyl)borate ( $\text{TpMe}_2$ ) complex  $(\text{TpMe}_2)_2\text{Sm}(\text{C}\equiv\text{CPh})$  results from the reaction of  $(\text{TpMe}_2)_2\text{Sm}$  with  $\text{Hg}(\text{C}\equiv\text{CPh})_2$  in THF.<sup>45</sup>

## 2.4 Lanthanide Alkylaluminates

Homoleptic (*see Homoleptic Compound*) alkylaluminates of the lanthanide metals like  $\text{Nd}[(\mu\text{-Me})_2\text{AlMe}_2]_3$  are formed when an excess of  $\text{AlMe}_3$  reacts with  $(\text{Me}_2\text{N})_3\text{Ln}$  complexes (equation 8). Earlier  $\text{Cp}_2\text{Ln}(\mu\text{-R})_2\text{AlR}_2$  (Ln = Sc, Y, Ga, Dy, Ho, Er, Tm, Yb, R = Me; Ln = Sc, Y, Ho, R = Et) have been prepared from  $(\text{Cp}_2\text{LnCl})_2$  with  $\text{Li}(\text{AlR}_4)$  or  $\text{Mg}(\text{AlR}_4)_2$ , as well as  $[\text{Cp}^*_2\text{Ln}(\mu\text{-Me}_2)\text{MMe}_2]_2$  (Ln = Y, Yb; M = Al, Ga),<sup>6</sup>  $[\text{Cp}^*_2\text{Yb}(\mu\text{-Me}_2)\text{AlMe}_2]_2$  and  $[\text{Cp}^*_2\text{Yb}(\text{S-}p\text{-tolyl})(\text{Me}_3\text{Al})_2]_2$ ,<sup>46</sup> and *rac*- $\text{Me}_2\text{Si}(2\text{-MeC}_9\text{H}_5)_2\text{Y}(\mu\text{-R})_2\text{AlR}_2$  (R = Me, Et, *iso*-Bu).<sup>47</sup>

**Figure 13**  $[(\text{quaph})\text{SmBr}(\text{THF})_2]_2$  (quaph = *o*-quaterphenyl)

The reaction of  $[\text{Cp}'_2\text{Y}(\mu\text{-Me})_2]$  ( $\text{Cp}' = \text{C}_5\text{H}_5, \text{C}_5\text{H}_4\text{SiMe}_3$ ) with  $\text{B}(\text{C}_6\text{F}_5)_3$  affords the complexes  $\text{Cp}'_2\text{Y}\{\text{MeB}(\text{C}_6\text{F}_5)_3\}$ . In  $(\eta^5\text{-Me}_3\text{SiC}_5\text{H}_4)_2\text{Y}\{(\mu\text{-FC}_6\text{F}_4)(\mu\text{-Me})\text{B}(\text{C}_6\text{F}_5)_2\}$ , the yttrium atom is coordinated in a chelating fashion via one ortho-F atom and agostic interactions (see *Agostic Bonding*) to Me groups. The alkylation of  $\text{Ln}(\text{O}^t\text{Bu})_3$  with  $\text{AlMe}_3$  leads to the mixed-bridged alkyl-alkoxy complexes  $\text{Ln}[(\mu\text{-O}^t\text{Bu})_3(\mu\text{-Me})\text{AlMe}_2]_3$  ( $\text{Ln} = \text{Pr}, \text{Nd}$  or  $\text{Y}$ ). Bis-trialkylaluminum adducts  $(\text{ArO})\text{Ln}[(\mu\text{-OAr})(\mu\text{-R})\text{AlR}_2]_2$  ( $\text{Ln} = \text{La}, \text{R} = \text{Me}; \text{Ln} = \text{La}, \text{R} = \text{Et}; \text{Ln} = \text{Sm}, \text{R} = \text{Et}$ ) were prepared by the reaction of  $[\text{Ln}(\text{OAr})_3]_2$  with four equiv. of trialkylaluminum.<sup>48</sup> Highly substituted lanthanide(III) aryloxide trimethylaluminum complexes are known.  $\text{Y}(\text{OC}_6\text{H}_3^i\text{Pr}_{2-2,6})[(\mu\text{-OC}_6\text{H}_3^i\text{Pr}_{2-2,6})(\mu\text{-Me})\text{AlMe}_2]_2$  and  $\text{Ln}(\text{OC}_6\text{H}_3^i\text{Bu}_{2-2,6})_2[(\mu\text{-Me})_2\text{AlMe}_2]$  ( $\text{Ln} = \text{Y}, \text{Lu}$ ) have been characterized by X-ray structures.<sup>49</sup> The reaction of  $\text{Nd}(\text{NPh})_3(\text{KCl})_3$  with  $\text{AlMe}_3$  afforded a heteroleptic mixed-metal complex  $\{[\text{Me}_2\text{Al}(\mu\text{-Me}_2)]_2\text{Nd}(\mu_3\text{-NPh})(\mu\text{-Me})\text{AlMe}_2\}$ .  $\text{Nd}[(\mu\text{-NMe}_2)(\mu\text{-Me})\text{MMe}_2]_3$  ( $\text{M} = \text{Al}, \text{Ga}$ ) were prepared from  $\text{Nd}(\text{NMe}_2)_3(\text{LiCl})_3$  and 3 equiv. of  $\text{MMe}_3$  ( $\text{M} = \text{Al}, \text{Ga}$ ) and the reaction of  $\text{Nd}(\text{NMe}_2)_3(\text{LiCl})_3$  with excess of  $\text{GaMe}_3$  gave homoleptic  $\text{Nd}\{(\mu\text{-Me})_2\text{GaMe}_2\}_3$ . Aluminates  $\{\text{AlMe}_2(\text{O}_2\text{CC}_6\text{H}_2^i\text{Pr}_{3-2,4,6})_2\text{LnAlMe}_4$  ( $\text{Ln} = \text{Y}, \text{La}, \text{Nd}, \text{Lu}$ ), supported by carboxylate ligands, are available from lanthanide tris(carboxylates) and  $\text{Me}_3\text{Al}$ . These aluminates are highly active in the polymerization of isoprene forming more than 99% cis polymers.<sup>50</sup>

## 2.5 Lanthanide Complexes with Carbenes, Ylides, Bis(imino)phosphoranides, and Phosphomethanides

Imidazolin-2-ylidenes  $\text{C}(\text{NRCHR}')_2$  react with coordinatively unsaturated organolanthanides and with THF or Lewis base stabilized organolanthanide complexes under replacement forming organolanthanide carbene adducts. Until now there are only a few examples of  $\text{Ln}(\text{III})$  carbene adducts known, for example,  $[(\text{Me}_2\text{HSi})_2\text{N}]_3\text{Y}(\text{C}_3\text{N}_2\text{H}_2\text{Me}_2)_n$  ( $\text{C}_3\text{N}_2\text{-H}_2\text{Me}_2 = 1,3\text{-dimethylimidazolin-2-ylidene}, n = 1, 2$ ) (Figure 15a),  $\text{L}_3\text{Eu}(\text{C}_3\text{N}_2\text{Me}_4)$  ( $\text{L} = 2,2,6,6\text{-tetramethylheptan-3,5-dionate}; \text{C}_3\text{N}_2\text{Me}_4 = 1,2,3,4\text{-tetramethylimidazolin-2-ylidene}$ ), and the silylene derivative  $\text{Cp}_3\text{LnSi}\{[\text{N}(\text{CH}_2^t\text{Bu})_2\text{-C}_6\text{H}_4\text{-1,2}]\}$  ( $\text{Ln} = \text{Y}, \text{Yb}$ ).<sup>51</sup> For carbene complexes of  $\text{Ln}(\text{II})$

**Figure 15** (a)  $[(\text{Me}_2\text{HSi})_2\text{N}]_3\text{Y}(\text{C}_3\text{N}_2\text{H}_2\text{Me}_2)_2$  and (b)  $(\text{COT})\text{-Cp}^*\text{YCH}_2\text{C}(\text{NMeCHMe})_2$

compounds, see Section 11.  $[(\text{Me}_3\text{Si})_2\text{N}]_3\text{Ln}$  ( $\text{Ln} = \text{La}, \text{Nd}$ ) and  $(\text{COT})\text{YCp}^*$  react with 1,3,4,5-tetramethylimidazolin-2-ylidene to yield the ylidic olefin complexes  $[(\text{Me}_3\text{Si})_2\text{N}]_3\text{Ln-CH}_2\text{C}(\text{NMeCHMe})_2$  and  $(\text{COT})\text{Cp}^*\text{YCH}_2\text{C}(\text{NMeCHMe})_2$  (Figure 15b) respectively.

Organolanthanide-phosphorus ylide complexes  $(\text{C}_5\text{-H}_4\text{R})_3\text{NdCH}_2\text{P}(\text{Me})\text{Ph}_2$  ( $\text{R} = \text{H}, ^t\text{Bu}$ ) and  $(\text{C}_5\text{H}_4^t\text{Bu})_2\text{Yb}(\text{Cl})\text{-CH}_2\text{P}(\text{Me})\text{Ph}_2$  were synthesized from  $\text{Li}[(\text{CH}_2)_2\text{PPh}_2]$  and the respective  $\text{Cp}_2\text{LnCl}$  precursors. Variable temperature  $^{31}\text{P}\{^1\text{H}\}$  NMR spectroscopy indicates an equilibrium between  $(\text{C}_5\text{H}_4\text{R})_3\text{NdCH}_2\text{P}(\text{Me})\text{Ph}_2$  and  $[(\text{C}_5\text{H}_4\text{R})_3\text{Nd}(\text{THF}) + \text{CH}_2=\text{P}(\text{Me})\text{Ph}_2]$  in THF solution. The bisiminophosphorane  $\text{CH}_2(\text{Ph}_2\text{P}=\text{NSiMe}_3)_2$  reacts with  $\text{Sm}(\text{NCy}_2)_3(\text{THF})$  in toluene to give  $[(\text{Ph}_2\text{P}=\text{NSiMe}_3)_2\text{C}]\text{Sm}(\text{NCy}_2)(\text{THF})$  (Figure 16).<sup>52</sup>

Phosphinomethanide complexes of the lanthanides  $[\text{Me}_3\text{SiC}(\text{PMe}_2)_2]_3\text{Lu}(\text{THF})$  and  $[\text{Me}_3\text{SiC}(\text{PMe}_2)_2]_3\text{Lu}$  are prepared by reaction of  $\text{Lu}(\text{OSO}_2\text{CF}_3)_3$  with  $\text{Li}[\text{Me}_3\text{SiC}(\text{PMe}_2)_2]$ . Alkylation with  $\text{MeLi}$  forms  $[\text{Me}_3\text{SiC}(\text{PMe}_2)_2]_2\text{-Lu}(\text{Me})(\text{THF})$  (Figure 17a). Reaction of  $\text{K}\{\text{CH}(\text{PPh}_2\text{NSiMe}_3)_2\}$  with  $\text{LnCl}_3$  forms  $\{[\text{CH}(\text{PPh}_2\text{NSiMe}_3)_2]\text{LnCl}_2\}_2$  ( $\text{Ln} = \text{Y}, \text{Sm}, \text{Er}, \text{Dy}, \text{Yb}, \text{Lu}$ ). Further reaction of the Y and Sm derivatives with  $\text{KNPh}_2$  affords  $\{[\text{CH}(\text{PPh}_2\text{NSiMe}_3)_2]\text{Ln}(\text{NPh}_2)_2\}$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ).<sup>53</sup> The corresponding dicyclopentadienyl complexes  $\text{Cp}_2\text{Ln}\{\text{CH}(\text{PPh}_2\text{NSiMe}_3)_2\}$  (Figure 17b)<sup>54</sup> are also known.

**Figure 16**  $[(\text{Ph}_2\text{P}=\text{NSiMe}_3)_2\text{C}]\text{Sm}(\text{NCy}_2)(\text{THF})$

**Figure 17** (a)  $[\text{Me}_3\text{SiC}(\text{PMe}_2)_2]_2\text{Lu}(\text{Me})(\text{THF})$ ,  
(b)  $\text{Cp}_2\text{Ln}\{\text{CH}(\text{PPh}_2\text{NSiMe}_3)_2\}$  ( $\text{Ln} = \text{Y}, \text{Sm}, \text{Er}$ )

**Figure 18** Dimeric  $\text{Cp}^*_2\text{LnSiH}(\text{SiMe}_3)_2$

## 2.6 $\sigma$ -Silyl-, Germyl-, and Stannyl-derivatives

$\text{Cp}^*_2\text{LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Sm}, \text{Nd}, \text{Y}$ ) and  $(\text{C}_5\text{Me}_4\text{-Et})_2\text{LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Sm}, \text{Nd}$ ) react with  $\text{H}_2\text{Si}(\text{SiMe}_3)_2$  to form the silyl complexes  $\text{Cp}^*_2\text{LnSiH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Sm}, \text{Nd}, \text{Y}$ ) and  $(\text{C}_5\text{Me}_4\text{Et})_2\text{LnSiH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Sm}, \text{Nd}$ ), respectively. The X-ray crystal structure of  $\text{Cp}^*_2\text{LnSiH}(\text{SiMe}_3)_2$  shows dimers in the solid state via intermolecular  $\text{Sm} \cdots \text{CH}_3 \cdots \text{Si}$  interactions (Figure 18). The samarium hydride  $[\text{Cp}^*_2\text{Sm}(\mu\text{-H})]_2$  reacts with  $o\text{-MeOC}_6\text{H}_4\text{SiH}_3$  via Si–H activation affording  $\text{Cp}^*_2\text{SmSiH}_2\text{-(OC}_6\text{H}_4\text{-OMe-2)}$ , which rapidly decomposes to the dimeric aryl complex  $[\text{Cp}^*_2\text{Sm}(\mu\text{-C}_6\text{H}_4\text{Me-2})]_2$ ,<sup>44</sup> and  $[\text{Cp}^*_2\text{Sm}(\mu\text{-H})]_2$  reacts with  $\text{PhSiH}_3$  forming  $[\text{Cp}^*_2\text{SmSiH}_3]_3$ , which reacts with benzophenone yielding  $\text{Cp}^*_2\text{SmOCPh}_2(\text{SiH}_3)$ .<sup>55</sup>  $[\text{Li}(\text{DME})_3][\text{Cp}_2\text{Ln}(\text{SiMe}_3)_2]$  ( $\text{Ln} = \text{Sm}, \text{Lu}$ ) was prepared from  $\text{Cp}_2\text{Ln}(\mu\text{-Cl}_2)\text{Na}(\text{DME})_2$  and  $\text{Me}_3\text{SiLi}$  in DME and the scandocene complexes  $\text{Cp}_2\text{Sc}(\text{ER}_3)(\text{THF})$  [ $\text{ER}_3 = \text{Si}(\text{SiMe}_3)_3, \text{Si}(\text{SiMe}_3)_2\text{Ph}, \text{Si}(\text{t-Bu})\text{Ph}_2, \text{SiPh}_3, \text{Ge}(\text{SiMe}_3)_3$ ] were prepared by reacting the appropriate silyl- or germyl-lithium reagent with  $(\text{Cp}_2\text{ScCl})_2$ .

## 3 ALKENE AND ALKYNE COMPLEXES

Organolanthanide(III) complexes with  $\eta^2$  coordinated alkene or alkyne ligands are very rare. For alkene complexes of  $\text{Ln}(\text{II})$  compounds, see Section 11. The coordination of the

olefinic double bond to Y in  $\text{Cp}^*_2\text{YCH}_2\text{CH}_2\text{CMe}_2\text{CH}=\text{CH}_2$  (equation 9) could be proved by NMR.

The reaction of *meso*-octaethylporphyrinogen (oepg) lanthanide complexes,  $[\{(\text{oepg})\text{Ln}\}\text{Na}(\text{THF})_2]$  ( $\text{L} = \text{Pr}, \text{Nd}$ ) with  $\text{NaC}_{10}\text{H}_8$  in an ethene atmosphere in the presence of 18-crown-6 (see *Crown Ethers*) in THF yields dimeric species, where the metals are bridged by the  $[\text{C}_2\text{H}_4]^{2-}$  anion. According to the X-ray crystal structure of the Nd derivative, the  $[\text{CH}_2\text{CH}_2]^{2-}$  unit is side-on bonded to the two metal atoms (Figure 19a).

Similar reaction in an acetylene atmosphere gives the neutral dimers  $[(\text{oepg})\text{Ln}]_2[(\mu\text{-C}_2)(\mu\text{-Na})_4]$ . X-ray crystal structure analysis of the neodymium derivative (Figure 19b) shows the acetylide dianion end on bonded to the two metal centers.

The reaction of  $\text{YCl}_3$  with  $\text{K}_2(\text{Ph}_2\text{C}=\text{CPh}_2)$  followed by cation exchange with  $\text{NaBPh}_4$  in THF yields  $[\text{Na}(\text{THF})_6][\text{Y}(\text{Ph}_2\text{C}=\text{CPh}_2)_2](\text{THF})_2$ . According to the X-ray crystal structure, the unit  $[\text{Y}(\text{Ph}_2\text{CCPh}_2)_2]^-$  has a sandwich-like structure in which each  $(\text{Ph}_2\text{CCPh}_2)^{2-}$  dianion has six carbon atoms oriented toward the metal center with Y–C distances between 2.518 and 2.689 Å.<sup>11</sup>

## 4 ALLYL AND ALLENYL COMPLEXES

Allyl complexes of the lanthanides are very efficient catalysts for stereospecific butadiene polymerization. The smaller size of the allyl anion compared to other ionic  $\pi$ -systems like  $\text{Cp}^-$  allows the formation of homoleptic anionic complexes of the type  $[(\text{allyl})_4\text{Ln}]^-$  with all four ligands  $\eta^3$ -bonded to the Ln metal. Complexes  $[\text{Li}(\text{dioxane})_n][\text{Ln}(\eta^3\text{-C}_3\text{H}_5)_4]$  ( $\text{Ln} = \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Gd}, n = 2$ ;  $\text{Ln} = \text{Y}, n = 2.5$ ;  $\text{Ln} = \text{La}, n = 3$ ),  $[\text{Li}_2(\text{THF})_n][\text{Ln}(\eta^3\text{-C}_3\text{H}_5)_5]$  ( $\text{Ln} = \text{Y}, \text{La}, n = 2.5$ ;  $\text{Ln} = \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}, n = 3$ ), and  $[\text{Li}_2(\text{dioxane})_n][\text{Ln}(\eta^3\text{-C}_3\text{H}_5)_5]$  ( $\text{Ln} = \text{Ce}, \text{Nd}, \text{Sm}, \text{Gd}, \text{Dy}, \text{Ho}, \text{Er}; n = 1, 3$ ) are available by treatment of anhydrous lanthanide trichlorides with

**Figure 19** (a)  $[\{Na(THF)(18\text{-crown-}6)\}_2(\mu\text{-dioxane})][\{(oepg)Nd\}Na(THF)_2]$  and (b)  $[(oepg)Nd]_2[(\mu\text{-C}_2)(\mu\text{-Na})_4]$

allyllithium (equation 10). Neutral tris(allyl)lanthanide complexes  $Ln(\eta^3\text{-C}_3\text{H}_5)_3(\text{dioxane})_n$  ( $Ln = \text{La}, n = 1.5$ ;  $Ln = \text{Nd}, n = 1$ ) are prepared from  $Li[Ln(\text{C}_3\text{H}_5)_4]$  ( $Ln = \text{La}$  or  $\text{Nd}$ ) via allyllithium abstraction with  $\text{BEt}_3$  in dioxane. The La derivative is a dimer  $[\{La(\eta^3\text{-C}_3\text{H}_5)_3(\eta^1\text{-dioxane})\}_2(\mu\text{-dioxane})]$ , whereas the Nd derivative forms a coordination polymer  $[Nd(\eta^3\text{-C}_3\text{H}_5)_3(\mu\text{-dioxane})]_n$ . Bis(allyl)- and mono(allyl)neodymium(III) compounds  $\text{Cp}^*\text{Nd}(\eta^3\text{-C}_3\text{H}_5)_2(\text{dioxane})$  and  $[Nd(\eta^3\text{-C}_3\text{H}_5)\text{Cl}(\text{THF})_5][\text{BPh}_4](\text{THF})$  were examined as catalysts for butadiene polymerization.<sup>56</sup>

The bis- and mono(allyl)neodymium(III) chlorides,  $\text{Nd}(\eta^3\text{-C}_3\text{H}_5)_2\text{Cl}(\text{THF})_{1.5}$  and  $\text{Nd}(\eta^3\text{-C}_3\text{H}_5)\text{Cl}_2(\text{THF})_2$ , were prepared by the reaction between  $\text{Nd}(\eta^3\text{-C}_3\text{H}_5)_3(\text{dioxane})$  and  $\text{NdCl}_3(\text{THF})_2$  in the corresponding molar ratio in THF. In combination with MAO, they catalyze the 1,4-*cis*-polymerization of butadiene in toluene and heptane, with extremely high activity and selectivity ( $\geq 98\%$ ). The bis( $\eta^3$ -allyl)lanthanum(III) halides  $\text{La}(\eta^3\text{-C}_3\text{H}_5)_2\text{X}(\text{THF})_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) are also available by partial protolysis of  $\text{La}(\eta^3\text{-C}_3\text{H}_5)_3(\text{dioxane})_{1.5}$  with  $\text{Me}_3\text{NHX}$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) in THF.

The allyl complexes  $[\text{Cp}'_2\text{Sm}(\text{C}_3\text{H}_5)]_n$  ( $\text{Cp}' = \text{'BuC}_5\text{H}_4$ ) and *ansa*- $\text{Me}_4\text{C}_2(\eta^5\text{-C}_5\text{H}_4)_2\text{Sm}(\text{C}_3\text{H}_5)_2\text{Li}(\text{DME})$  were synthesized from  $(\text{Cp}'_2\text{SmCl})_2$  and *ansa*- $\text{Me}_4\text{C}_2(\eta^5\text{-C}_5\text{H}_4)_2\text{SmCl}[\text{MgCl}_2(\text{THF})_4]$ , respectively. The mono-allyl complex

$\text{Cp}^*_2\text{Sm}(\eta^3\text{-C}_3\text{H}_5)$  reacts with  $\text{CO}_2$  in toluene at room temperature to form  $[\text{Cp}^*_2\text{Sm}(\mu\text{-O}_2\text{CCH}_2\text{CH}=\text{CH}_2)]_2$ . In THF it exists as solvated monometallic species  $\text{Cp}^*_2\text{Sm}(\mu_2\text{-O}_2\text{CCH}_2\text{CH}=\text{CH}_2)(\text{THF})$  but it crystallizes from hexane as a bimetallic complex that contains an eight-membered  $\text{SmO-COSmOCO}$  ring (equation 11).

Variable temperature  $^1\text{H}$  NMR spectroscopy of a series of Sc and Y metallocene allyl complexes indicates fluxional (see *Fluxional Molecule* and **Structure & Property Maps for Inorganic Solids**) behavior involving C-C

double-bond dissociation from the metal center, that is, an  $\eta^3$  to  $\eta^1$  change in coordination. Activation barriers to olefin dissociation were determined for  $\eta^5$ -Cp\*<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>), *meso*-Me<sub>2</sub>Si( $\eta^5$ -3-*t*BuC<sub>5</sub>H<sub>3</sub>)<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>), *meso*-Me<sub>2</sub>Si( $\eta^5$ -2,4-*i*Pr<sub>2</sub>C<sub>5</sub>H<sub>2</sub>)<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>), *meso*-Me<sub>2</sub>Si( $\eta^5$ -3-[2-(2-Me)adamantyl]C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>), *meso*-Me<sub>2</sub>Si( $\eta^5$ -3-[2-(2-Me)adamantyl]C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>Y(C<sub>3</sub>H<sub>5</sub>), *rac*-Me<sub>2</sub>Si( $\eta^5$ -2,4-*i*Pr<sub>2</sub>C<sub>5</sub>H<sub>2</sub>)<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>), and (*R*)-(C<sub>20</sub>H<sub>12</sub>O<sub>2</sub>)Si( $\eta^5$ -2-SiMe<sub>3</sub>-4-*t*BuC<sub>5</sub>H<sub>2</sub>)<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>). It has been found that donor solvents do not significantly affect the rate of this process. X-ray structure analysis of *rac*-Me<sub>2</sub>Si( $\eta^5$ -2,4-*i*Pr<sub>2</sub>C<sub>5</sub>H<sub>2</sub>)<sub>2</sub>Sc(C<sub>3</sub>H<sub>5</sub>) showed the allyl ligand  $\eta^3$  coordinated to the metal.<sup>11</sup>

The reaction of Li<sub>2</sub>[(Me<sub>3</sub>Si)<sub>2</sub>C<sub>5</sub>H<sub>2</sub>]SiMe<sub>2</sub>(CHC≡CSiMe<sub>3</sub>) with SmCl<sub>3</sub> yields the allenyl complex {[(Me<sub>3</sub>Si)<sub>2</sub>C<sub>5</sub>H<sub>2</sub>]SiMe<sub>2</sub>( $\eta^3$ -CH=C=CSiMe<sub>3</sub>)}SmCl<sub>3</sub>Li<sub>2</sub>(TMEDA)<sub>2</sub>, whereas the reaction of the dilithium salt of the triphenylsilyl substituted ligand with SmCl<sub>3</sub> yielded the  $\eta^1$ -propargyl derivative {[(Me<sub>3</sub>Si)<sub>2</sub>C<sub>5</sub>H<sub>2</sub>]SiMe<sub>2</sub>( $\eta^1$ -CHC≡CSiPh<sub>3</sub>)}Sm(TMEDA)[Cl<sub>2</sub>Li(TMEDA)]. A conversion of the bonding mode from  $\eta^1$ -propargyl to  $\eta^3$ -allenyl was observed when the later compound was treated with (Me<sub>3</sub>Si)<sub>3</sub>CLi/LiI to give the  $\eta^3$ -allenyl complex {[(Me<sub>3</sub>Si)<sub>2</sub>(C<sub>5</sub>H<sub>2</sub>)]SiMe<sub>2</sub>( $\eta^3$ -CH=C=CSiPh<sub>3</sub>)}SmI<sub>2</sub>Li(TMEDA) (equation 12).<sup>57</sup>

Thermal decomposition of Me<sub>2</sub>Si(C<sub>5</sub>Me<sub>4</sub>)(CH<sub>2</sub>CH=CH<sub>2</sub>)Y(CH<sub>2</sub>SiMe<sub>3</sub>)<sub>2</sub>(THF)<sub>2</sub>, containing an allyl(dimethylsilyl)substituted cyclopentadienyl ligand, yields [Y{ $\eta^5$ : $\eta^1$ -C<sub>5</sub>Me<sub>4</sub>SiMe<sub>2</sub>( $\mu$ - $\eta^3$ -C<sub>3</sub>H<sub>3</sub>)}L]<sub>2</sub> (L = DME or THF). X-ray diffraction studies showed that the novel trianionic ligand bridges the two yttrium atoms by coordinating  $\eta^5$ : $\eta^1$  to one and  $\eta^3$  to the other metal (Figure 20).<sup>58</sup>

Several lanthanide(II) and lanthanide(III) complexes with aza-allyl ligands Ln(L)<sub>2</sub>X(THF)<sub>n</sub> (L =  $\eta^3$ -Me<sub>3</sub>SiN=C(*t*Bu)-CHSiMe<sub>3</sub>; X = Cl, *n* = 1, Ln = Ce or Nd; X = I, *n* = 1, Ln = Sm; X = I, *n* = 0, Ln = Yb), Sm(L)<sub>2</sub>(THF) and Yb(L)<sub>2</sub>, were synthesized by the reaction of the appropriate

Figure 20 [Y{ $\eta^5$ : $\eta^1$ -C<sub>5</sub>Me<sub>4</sub>SiMe<sub>2</sub>( $\mu$ - $\eta^3$ -C<sub>3</sub>H<sub>3</sub>)}THF]<sub>2</sub>

lanthanide(II) or lanthanide(III) halides with two equiv. of 1,3-bis(trimethylsilyl)-1-aza-allylpotassium.

## 5 DIENE COMPLEXES

Lanthanide complexes with neutral coordinated diene ligands are unknown. In contrast, a few examples containing anionic diene ligands, for example, [Cp\*<sub>2</sub>La(THF)( $\mu$ - $\eta^1$ ,  $\eta^3$ -C<sub>4</sub>H<sub>6</sub>)LaCp\*<sub>2</sub>] and [LaI<sub>2</sub>(THF)<sub>3</sub>]<sub>2</sub>( $\mu$ -Ph<sub>2</sub>C<sub>4</sub>H<sub>4</sub>), have been described.<sup>6</sup> The related gadolinium complex [GdCl<sub>2</sub>(THF)<sub>3</sub>]<sub>2</sub>( $\mu$ -Ph<sub>2</sub>C<sub>4</sub>H<sub>4</sub>) was obtained by the reaction of GdCl<sub>3</sub> with potassium diphenylbutadienide generated in situ.<sup>4</sup> The structurally characterized lutetium compound [( $\mu$ -PhCHCHCHCHPh)<sub>2</sub>Lu(THF)<sub>2</sub>K(THF)<sub>2</sub>]<sub>n</sub> contains two  $\eta^4$ -diphenylbutadiene ligands and two THF molecules coordinated to the central lutetium ion. The diphenylbutadiene is bonded in its *cis* conformation. In the crystal, a polymeric chain structure results from additional  $\eta^6$ -coordination of two phenyl rings to potassium. Since the oxidation state of lutetium is +3, the two diene ligands must be formally dianions to result in a monoanionic species with potassium as the counterion (Figure 21).<sup>11</sup>

Pentamethylcyclopentadienyllanthanide dichlorides Cp\*<sub>2</sub>-LnCl<sub>2</sub> (Ln = Sm, Lu) react with diarylbutadienes and lithium under elimination of the pentamethylcyclopentadienyl

Figure 21 [( $\mu$ -PhCHCHCHCHPh)<sub>2</sub>Lu(THF)<sub>2</sub>K(THF)<sub>2</sub>]<sub>n</sub>

ligand and formation of anionic (butadiene)lanthanide complexes  $[\text{Li}(\text{THF})_3][\text{Sm}(1,4\text{-Ph}_2\text{C}_4\text{H}_4)_2]$  and  $[\text{Li}(\text{DME})][\text{Lu}(1,4\text{-Ar}_2\text{C}_4\text{H}_4)\text{LuCl}_2]$  (in THF and DME, respectively). A slightly different lithium salt  $[\text{Li}(\text{THF})_3][\text{Sm}(1,4\text{-Ph}_2\text{C}_4\text{H}_4)_2]$  was isolated in the form of black–red crystals starting directly from  $\text{SmCl}_3$ . A mononuclear samarium complex  $[\text{1,4-(p-MeC}_6\text{H}_4)_2\text{C}_4\text{H}_4]\text{SmI}(\text{THF})_3$  containing a terminal 1,4-di-*p*-tolylbutadiene ligand results from the reaction of metallic samarium with iodine and the butadiene derivative in THF.

The reduction of diphenylacetylene with  $[\text{CpLu}(\text{C}_{10}\text{H}_8)(\text{DME})]^{2-}$  results in C–C coupling and formation of a dinuclear complex with a bridging  $[\text{C}_4\text{Ph}_4]^{4-}$  ligand:  $[\text{CpLu}(\text{DME})_2][\mu\text{-}\eta^4\text{:}\eta^4\text{-PhCC(Ph)=C(Ph)CPh}]$ . The crystallographic and spectral data suggest a dialkylidene bridging ligand in this complex.<sup>11</sup>

$\text{CpLuCl}_2(\text{THF})_2$  reacts with 2 equiv. of  $\text{Na}[\text{PhCH=CHPh}]$  in DME with dimerization of the stilbene radical anions to form  $[\text{Na}(\text{DME})_3][\text{Cp}_2\text{Lu}\{\mu\text{-CH(Ph)CH(Ph)-CH(Ph)CH(Ph)}\}]$  containing a dianionic 1,2,3,4-tetraphenylbutadiene ligand. X-ray crystal structure determination shows Lu coordinated to two Cp rings and the dianionic butadiene ligand in an  $\eta^5$  and 1,4-diyl fashion.<sup>59</sup>

A nonreductive reaction pathway has been also used for coupling of alkynes to produce complexes with dianionic butadiene ligands. Thus, the reaction of  $\text{Cp}^*_2\text{LaCH}(\text{SiMe}_3)_2$  with  $\text{PhC}\equiv\text{CH}$  at room temperature yields the binuclear product  $(\text{Cp}^*_2\text{La})_2(\mu\text{-Ph}_2\text{C}_4)$  and  $\text{CH}_2(\text{SiMe}_3)_2$ . Although the uncoupled dimer  $(\text{Cp}^*_2\text{LaC}_2^t\text{Bu})_2$  is formed in the reaction of  $\text{Cp}^*_2\text{LaCH}(\text{SiMe}_3)_2$  with  $^t\text{BuC}\equiv\text{CH}$  at 0 °C, it undergoes clean unimolecular conversion in toluene solution at 60 °C to the coupled dimer  $(\text{Cp}^*_2\text{La})_2(\mu\text{-}^t\text{Bu}_2\text{C}_4)$ . The related Sm(III) complex  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-Ph}_2\text{C}_4)$  has been prepared using both reductive and nonreductive conditions reacting  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  and  $\text{PhC}\equiv\text{C-C}\equiv\text{CPh}$  or by thermolysis of  $\text{Cp}^*_2\text{Sm}(\text{C}\equiv\text{CPh})(\text{THF})$  at 80–145 °C. The later compound can be prepared also from  $\text{PhC}\equiv\text{CH}$  and  $[\text{Cp}^*_2\text{SmH}]_2$  or  $\text{Cp}^*_2\text{Sm}[\text{CH}(\text{SiMe}_3)_2]$ .<sup>6</sup>

## 6 PENTADIENYL COMPLEXES

Owing to relationship between cyclopentadienyl and pentadienyl ligands, the complexes of the later ligand are often termed *open metallocenes*. Lanthanide derivatives with ‘open cyclopentadienyl ligands’ have been described since 1982, for example,  $\text{Tris}(2,4\text{-dimethylpentadienyl})\text{neodymium Nd}(\text{C}_7\text{H}_{11})_3$ . The X-ray crystal structure shows three equivalent  $\eta^5$ -coordinated 2,4-dimethylpentadienyl ligands. The related complexes of La, Sm, Gd, Tb, and Lu are also known. Owing to the smaller ionic radius of  $\text{Lu}^{3+}$  only two 2,4-dimethylpentadienyl ligands are  $\eta^5$ -coordinated in the Lu derivative, while the third ligand is bonded to lutetium in an  $\eta^3$ -allyl-like fashion. Later work showed the formation of a minor by-product, which has been

**Figure 22**  $\text{Lu}(\eta^5\text{-C}_7\text{H}_{11})(\eta^5\text{:}\eta^3\text{-MeC}_5\text{H}_5\text{CH}_2\text{CH}_2\text{CHMeC}_3\text{H}_3\text{Me})$

shown by X-ray crystallography to be  $\text{Lu}(\eta^5\text{-C}_7\text{H}_{11})(\eta^5\text{:}\eta^3\text{-MeC}_5\text{H}_5\text{CH}_2\text{CH}_2\text{CH}(\text{Me})\text{C}_3\text{H}_3(\text{Me}))$ , containing a dimeric chelate ligand derived from end-to-end fusion of two 2,4-dimethylpentadienyl groups (Figure 22).<sup>11</sup>

Homoleptic tris(2,4-dimethylpentadienyl) derivatives of gadolinium and erbium have been used to synthesize phenylalkynyl derivatives via reactions with equimolar amounts of phenylacetylene (equation 13)

Several other pentadienyllanthanide complexes have been reported, including the mono(pentadienyl) derivatives  $(\eta^5\text{-C}_7\text{H}_{11})\text{LnCl}_2(\text{THF})_3$  ( $\text{Ln} = \text{Nd}, \text{Sm}, \text{Gd}$ ) and bis(pentadienyl)lanthanide halides  $(\eta^5\text{-C}_7\text{H}_{11})_2\text{LnCl}(\text{THF})$  ( $\text{Ln} = \text{Nd}, \text{Sm}, \text{Gd}$ ). The mono(pentadienyl) derivative  $(\eta^5\text{-C}_7\text{H}_{11})\text{NdCl}_2$  is a hexamer  $(\eta^5\text{-C}_7\text{H}_{11})_6\text{Nd}_6\text{Cl}_{12}(\text{THF})_2$ , which consists of two  $\text{Nd}_3\text{Cl}_5$  entities connected via two chloro bridges. The structure of the  $\text{Nd}_3\text{Cl}_5$  moiety contains a distorted hexagonal bipyramidal polyhedron with  $\text{C}_7\text{H}_{11}$  anions connected to the neodymium atoms in a  $\eta^5$  fashion.<sup>11</sup> The reaction of  $\text{LnCl}_3$  ( $\text{Ln} = \text{Nd}, \text{Er}$ ) with  $\text{K}_2\text{COT}$  followed by treatment with  $\text{K}(\text{C}_7\text{H}_{11})$  gave  $(\text{COT})\text{Ln}(\eta^5\text{-C}_7\text{H}_{11})(\text{THF})$ .

## 7 CYCLOPENTADIENYL, INDENYL, & FLUORENYL COMPLEXES

Most of all organometallic compounds of the rare earth metals known to date are cyclopentadienyl complexes. There is a large variety of cyclopentadienyl derivatives used as ligands such as mono-, bis-, and poly-substituted moieties; cyclopentadienides containing donor-functionalized substituents; bridged bis-cyclopentadienides forming ansa complexes; cyclopentadienide ligands with other adjacent  $\pi$ -coordinating ligands like carboranes or pyrroles; and annelated ligands with cyclopentadienyl segments such as indenyls and fluorenyls. A complete survey of this class of organolanthanides up to 1994 is given in Ref. 6. Later reviews are published in 2002.<sup>8</sup> This chapter deals only with tris(cyclopentadienyl)lanthanide complexes, bis(cyclopentadienyl)lanthanide and mono(cyclopentadienyl)lanthanide derivatives in which the lanthanide is

bonded to elements other than carbon besides the cyclopentadienyl ligands, and corresponding complexes with annelated cyclopentadienyl ligands. For bis(cyclopentadienyl)lanthanide and mono(cyclopentadienyl)lanthanide alkyl, aryl, alkene, alkyne, or allyl complexes, see Sections 2 to 6.

### 7.1 Tris(cyclopentadienyl) Complexes

Tris(cyclopentadienyl)lanthanide complexes are prepared by salt elimination from the corresponding lanthanide trichlorides and NaCp or KCp in Et<sub>2</sub>O, THF, or benzene. In contrast to cyclopentadienyl complexes of the transition metals, the bonding of the lanthanide atoms to the cyclopentadienyl ring is best described as ionic with only little participation of covalency. Thus, the <sup>151</sup>Eu Moessbauer spectra of CpEuCl<sub>2</sub>(THF)<sub>3</sub>, CpEu(NCO)<sub>2</sub>(THF), and CpEu(NCS)<sub>2</sub>(THF)<sub>3</sub> have been measured at 4.2 K and show hyperfine parameters that are normal for organoeuropium(III) compounds, whereas the Moessbauer spectrum of Cp<sub>3</sub>Eu(THF) is very different with a negative isomer shift of  $-1.77 \text{ mm s}^{-1}$  and a large negative quadrupole interaction of  $-33.6 \text{ mm s}^{-1}$ . This isomer shift corresponds to the transfer of ca. 0.14 electrons from the cyclopentadienyl ligands into the 4f orbitals of europium via covalent bonding. Most tris(cyclopentadienyl)lanthanide complexes have been investigated by X-ray crystallography. The structure is highly dependent on the size of the metal. A strictly monomeric compound with three  $\eta^5$ -Cp ligands is found for Yb only. The smaller Sc and Lu (Figure 23) have a reduced formal coordination number of eight with two  $\eta^5$ -Cp ligands and two bridging  $\eta^1$ -Cp ligands so that a polymeric chain results. The larger metals increase their coordination number gradually by weak van der Waals interactions [Y, Er (Figure 24), Tm] or by increasing coordination [Nd:  $\eta^1$ -Cp; Pr:  $\eta^{1-2}$ -Cp; La:  $\eta^2$ -Cp (Figure 25)] to neighboring Cp<sub>3</sub>Ln units so that polymeric chains are also formed.<sup>6</sup>

Figure 23 Structure of Cp<sub>3</sub>Lu

Figure 24 Structure of Cp<sub>3</sub>Er

Figure 25 Structure of Cp<sub>3</sub>La

A series of homoleptic substituted tris(cyclopentadienyl)lanthanide(III) complexes Cp<sup>R</sup><sub>3</sub>Ln (Ln = La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Er, Tm, Yb), Cp<sup>t</sup><sub>3</sub>Nd, Cp<sup>u</sup><sub>3</sub>Ce, Cp<sup>u</sup><sub>3</sub>Nd [Cp<sup>R</sup> =  $\eta^5$ -C<sub>5</sub>H<sub>4</sub>CH(SiMe<sub>3</sub>)<sub>2</sub>, Cp<sup>t</sup> =  $\eta^5$ -C<sub>5</sub>H<sub>4</sub>(SiMe<sub>2</sub><sup>t</sup>Bu), Cp<sup>u</sup> =  $\eta^5$ -C<sub>5</sub>H<sub>3</sub>(SiMe<sub>2</sub><sup>t</sup>Bu)<sub>2-1,3</sub>], and [(Me<sub>3</sub>Si)<sub>2</sub>C<sub>5</sub>H<sub>3</sub>]<sub>3</sub>Ln (Ln = La, Nd, Sm, Gd or Dy) have been synthesized by reaction of anhydrous lanthanide(III) halides with the appropriate sodium or potassium cyclopentadienide in THF. Mixed cyclopentadienyl complexes Cp<sup>\*</sup><sub>2</sub>CpLn (Ln = La, Nd) were prepared by ring metathesis between Cp<sup>\*</sup><sub>2</sub>Ca and Cp<sub>3</sub>Ln in toluene. Only one ring is exchanged between Cp<sup>\*</sup><sub>2</sub>Ca(THF) and Cp<sub>3</sub>La(THF) in toluene to yield Cp<sup>\*</sup>Cp<sub>2</sub>La(THF). The trichlorides of La, Nd, Sm, and Tb react with Na(C<sub>5</sub>HMe<sub>4</sub>) in THF to yield the homoleptic complexes (C<sub>5</sub>HMe<sub>4</sub>)<sub>3</sub>Ln (Ln = La, Nd, Sm, Tb). On the other hand, the reactions of HoCl<sub>3</sub>, TmCl<sub>3</sub>, and LuCl<sub>3</sub> with Na(C<sub>5</sub>HMe<sub>4</sub>) result only with formation of the dicyclopentadienyl complexes (C<sub>5</sub>HMe<sub>4</sub>)<sub>2</sub>LnCl(THF) (Ln = Ho, Tm, Lu).

Tris(cyclopentadienyl)lanthanide complexes with sterically more crowded Cp ligands such as C<sub>5</sub>Me<sub>4</sub>R (R = Me, Et, <sup>i</sup>Pr, and SiMe<sub>3</sub>) are not assessable by simple metathesis between lanthanide trihalides and the respective alkali metal salt of the bulky Cp ligand. For instance, Cp<sup>\*</sup><sub>3</sub>Sm, obtainable from Cp<sup>\*</sup><sub>2</sub>Sm and cyclooctatetraene, reacts with THF with ring-opening forming Cp<sup>\*</sup><sub>2</sub>Sm[O(CH<sub>2</sub>)<sub>4</sub>Cp<sup>\*</sup>](THF) (equation 14).

(14)

However,  $\text{Cp}^*_2\text{Sm}(\text{OEt}_2)$  reacts cleanly with  $\text{Cp}^*_2\text{Pb}$  to give  $\text{Cp}^*_3\text{Sm}$  in  $>90\%$  yield. This route has been used to synthesize the more sterically crowded  $(\text{C}_5\text{Me}_4\text{Et})_3\text{Sm}$ . In general,  $(\text{C}_5\text{Me}_4\text{R})_3\text{La}$  ( $\text{R} = \text{Me}, \text{Et}, ^i\text{Pr}, \text{SiMe}_3$ ) complexes can be prepared in four steps by reaction of  $\text{LaCl}_3$  with  $\text{KC}_5\text{Me}_4\text{R}$  to form  $(\text{C}_5\text{Me}_4\text{R})_2\text{LaCl}_2\text{K}(\text{THF})_2$ , followed by addition of allylmagnesium chloride to produce  $(\text{C}_5\text{Me}_4\text{R})_2\text{La}(\text{C}_3\text{H}_5)$ , then protonolysis with  $\text{Et}_3\text{NHBPh}_4$  yielding  $[(\text{C}_5\text{Me}_4\text{R})_2\text{La}][\text{BPh}_4]$ , and finally by replacement of  $\text{BPh}_4^-$  with  $\text{C}_5\text{Me}_4\text{R}^-$  using  $\text{KC}_5\text{Me}_4\text{R}$  affording  $(\text{C}_5\text{Me}_4\text{R})_3\text{La}$  (equation 15). X-ray crystallography shows monomer complexes  $(\text{C}_5\text{Me}_4\text{R})_3\text{La}$  ( $\text{R} = \text{Me}, \text{Et}, ^i\text{Pr}, \text{SiMe}_3$ ) with three  $\text{C}_5\text{Me}_4\text{R}$  ring centroids defining a trigonal planar geometry around the La atom.<sup>60</sup>

Related tris(peralkylcyclopentadienyl) complexes were also reported for smaller lanthanides than Nd and Sm. Such lanthanide(III) complexes behave as one-electron reductants, although the oxidation state of the metal retains +3. Thus,

$\text{Cp}^*_3\text{Nd}$  reduces  $\text{Ph}_3\text{P}=\text{Se}$  to  $\text{Ph}_3\text{P}$  forming  $\{\text{Cp}^*_2\text{Nd}\}_2(\mu-\eta^2:\eta^2-\text{Se}_2)$  (equation 16).  $\text{Cp}^*_3\text{Sm}$  reacts with a variety of substrates including CO, THF, ethylene, hydrogen, nitriles, isonitriles, isocyanates, cyclooctatetraene, azobenzene, and  $\text{Ph}_3\text{P}=\text{E}$  ( $\text{E} = \text{O}, \text{S}, \text{Se}$ ). Depending on the substrate,  $\text{Cp}^*_3\text{Sm}$  can react either as a bulky alkyl complex  $\text{Cp}^*_2\text{SmR}$  with  $\text{R} = \eta^1-\text{C}_5\text{Me}_5$  or as zwitterionic  $[\text{Cp}^*_2\text{Sm}]^+ [\text{Cp}^*]^-$  with the  $[\text{Cp}^*]^-$  anion as the one-electron reductant.

Tris(cyclopentadienyl)lanthanides form adducts with a variety of neutral Lewis bases such as THF; esters; sulfoxides; phosphineoxides, for example,  $(\text{C}_5\text{H}_4\text{PPh}_2)_3\text{Ln}(\text{OPPh}_3)$  ( $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Er}, \text{Y}$ );  $\text{NH}_3$ ; various amines, for example,  $\text{Cp}_3\text{Ln}(\text{Nic})$  ( $\text{Nic} = (S)-(-)\text{-nicotine}$ )<sup>61</sup> and  $\text{Cp}_3\text{Yb}(\text{NC}_4\text{H}_4\text{N})\text{YbCp}_3$ ; phosphines, for example,  $(\text{C}_5\text{H}_4\text{Me})_3\text{Yb}(\text{PMe}_3)$ ; nitriles, for example,  $\text{Cp}_3\text{Sm}(\text{NCCH}_3)$  and  $\text{Cp}_3\text{Pr}(\text{NC}_6\text{H}_{11}\text{-}c)$ ; and anions like halides, for example,  $[\text{Cp}_3\text{Ln}(\mu\text{-Cl})\text{LnCp}_3]^-$  or azide, for example,  $[\text{Cp}_3\text{Sm}(\mu\text{-N}_3)\text{SmCp}_3]^-$  (equation 17).

**Figure 26** (a)  $[\eta^5\text{-C}_5\text{H}_4\text{CH}((\text{CH}_2)_2)_2\text{NMe}_2]_3\text{Y}$  and (b)  $(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{OMe})_3\text{Nd}$

Stabilization by Lewis base donors can also be achieved by using donor-substituted cyclopentadienyl ligands, as shown in  $[\eta^5\text{-C}_5\text{H}_4\text{CH}((\text{CH}_2)_2)_2\text{NMe}_2]_3\text{Y}^{62}$  (Figure 26a) or in  $(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{OMe})_3\text{Ln}$  ( $\text{Ln} = \text{La}, \text{Pr}, \text{Nd}, \text{Gd}$  or  $\text{Y}$ ) (Figure 26b). Crystal structure determinations revealed that, in these unsolvated monomeric metallocenes, the lanthanide metals are coordinated by three cyclopentadienyl rings and two oxygen atoms whereas the third oxygen atom is not coordinated. A similar situation is observed in the phosphorus-functionalized complex  $[\text{Cp}(\text{CH}_2)_2\text{PMe}_2]_3\text{La}$ .

Bis(pentamethylcyclopentadienyl)phosphophyl and -arsolyl-samarium(III) complexes  $\text{Cp}^*_2\text{SmL}$  ( $\text{L} = \text{C}_4\text{H}_2\text{Me}_2\text{P}, \text{C}_4\text{H}_2'\text{Bu}_2\text{P}, \text{C}_4\text{Me}_4\text{P}, \text{C}_4\text{H}_2\text{Me}_2\text{As}$ ) are synthesized either by reaction of  $\text{Cp}^*_2\text{Sm}(\text{Et}_2\text{O})_x$  ( $x = 0, 1$ ) with  $(\text{C}_4\text{H}_2\text{Me}_2\text{P})_2$ ,  $(\text{C}_4\text{H}_2'\text{Bu}_2\text{P})_2$ ,  $(\text{C}_4\text{Me}_4\text{P})_2$ ,  $(\text{C}_4\text{H}_2\text{Me}_2\text{As})_2$ , or with  $\text{Ti}[\text{C}_4\text{Me}_4\text{P}]$  (equation 18).<sup>63</sup>

Tris(indenyl)lanthanide complexes of all rare earth metals can be prepared analogously from the lanthanide trichlorides with alkali or magnesium indenyl salts.<sup>6</sup> All five-membered rings are  $\eta^5$ -bonded to the metal. They form base adducts with

**Figure 27**  $(1\text{-C}_4\text{H}_7\text{-}4,7\text{-Me}_2\text{C}_9\text{H}_4)_3\text{La}(\mu\text{-Cl})\text{Li}(\text{Et}_2\text{O})_3$

THF and pyridine, with (*S*)-(-)-nicotine,<sup>61</sup> and with bridging chloride or LiCl (Figure 27).<sup>64</sup>

## 7.2 Bis(cyclopentadienyl) Complexes

The organometallic chemistry of the rare earths deals mainly with bis(cyclopentadienyl) derivatives due to the easy available bis(cyclopentadienyl) rare earth chlorides and other halides via reaction of the rare earth trichlorides with two equivalents of a cyclopentadienyl alkali salt. Bis(cyclopentadienyl)lanthanide chlorides are formed as chloride-bridged dimers (Figure 28a), as monomers stabilized by a donor molecule like THF (Figure 28b) or as *ate* complexes with alkali halides (Figure 28c).

A lot of corresponding derivatives are known derived of substituted cyclopentadienyl ligands, for example,  $(\text{C}_5\text{H}_4\text{Me})_2\text{LnCl}$ ,  $(\text{C}_5\text{H}_4'\text{Bu})_2\text{LnCl}$ ,  $(\text{C}_5\text{HMe}_4)_2\text{LnCl}$ ,  $\text{Cp}^*_2\text{-LnCl}$ ,  $(\text{Me}_3\text{SiC}_5\text{H}_4)_2\text{LnCl}$ ,  $[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_2\text{LnCl}$ , or  $(\text{PhCH}_2\text{C}_5\text{H}_4)_2\text{LnCl}(\text{THF})$  ( $\text{Ln} = \text{Gd}, \text{Er}$ ). Bis(cyclopentadienyl) ytterbium and samarium halides can be prepared by oxidation of  $\text{Cp}_2\text{Ln}(\text{II})$ , for example,  $\text{Cp}_2\text{YbX}(\text{THF})_n$  ( $\text{X} = \text{Cl}, n = 0.5$ ;  $\text{X} = \text{Br}$  or  $\text{I}, n = 1$ ) oxidation of  $\text{Cp}_2\text{Yb}(\text{DME})$  with  $\text{C}_2\text{Cl}_6$  or  $(\text{CH}_2\text{X})_2$  ( $\text{X} = \text{Br}$  or  $\text{I}$ ) in THF, and  $(\text{Cp}_2\text{YbX})_2$  analogously from unsolvated  $\text{Cp}_2\text{Yb}$  in petroleum ether.<sup>6</sup>

Hydrofluorination of  $[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_3\text{Ln}$  or  $\text{Cp}_3\text{Ln}$  in THF with 1 equiv. of  $\text{Me}_3\text{NHF}$  gave  $[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_2\text{LnF}]_2$  ( $\text{Ln} = \text{La}, \text{Nd}, \text{Sm}, \text{Gd}$ ) or  $[\text{Cp}_2\text{LnF}(\text{THF})]_2$  ( $\text{Ln} = \text{Y}, \text{Yb}$ ),

**Figure 28** (a)  $\text{Cp}_2\text{Ln}(\mu\text{-Cl})_2\text{LnCp}_2$ , (b)  $\text{Cp}_2\text{LnCl}(\text{THF})$ , and (c)  $\text{Cp}_2\text{Ln}(\mu\text{-Cl})_2\text{Li}(\text{THF})_2$

**Figure 29**  $[(\text{C}_5\text{H}_4\text{Me})_2\text{YbF}]_4$

correspondingly. Oxidation of  $\text{Cp}_2\text{Yb}$  and  $(\text{C}_5\text{H}_4\text{Me})_2\text{Yb}$  with perfluoro(methylcyclohexane) or perfluorodecalin in DME gave unsolvated  $(\text{Cp}_2\text{YbF})_3$  and  $[(\text{C}_5\text{H}_4\text{Me})_2\text{YbF}]_4$ , while in THF, the oxidation of  $(\text{C}_5\text{H}_4\text{Me})_2\text{Yb}$  provided the dimeric  $[(\text{C}_5\text{H}_4\text{Me})_2\text{YbF}(\text{THF})]_2$ .  $(\text{Cp}_2\text{YbF})_3$  is a trimer with formal eight-coordination for ytterbium and a planar  $(\text{YbF})_3$  ring, whereas  $[(\text{C}_5\text{H}_4\text{Me})_2\text{YbF}]_4$  is an eight-coordinate tetramer having a puckered  $(\text{YbF})_4$  unit (Figure 29).<sup>65</sup> The organosamarium fluoride  $[(\text{C}_5\text{H}_4'\text{Bu})_2\text{Sm}(\mu\text{-F})]_3$  was generated by oxidation of  $(\text{C}_5\text{H}_4'\text{Bu})_2\text{Sm}(\text{THF})_2$  with  $\text{Me}_3\text{SnF}$ .

$[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_2\text{YbI}(\text{THF})$  was synthesized by the reaction of two equivalents of  $\text{Na}[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]$  with  $\text{YbI}_3(\text{THF})_2$ .<sup>66</sup> Related complexes  $[(\text{Me}_3\text{Si})_2(\text{C}_5\text{H}_3)_2\text{LnI}(\text{THF})]$  ( $\text{Ln} = \text{La}, \text{Sm}, \text{Y}, \text{Er}, \text{Lu}$ ) were prepared by treatment of  $[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]_2\text{LnCl}_2$  with excess of  $\text{NaI}$  in dry

THF, or by reaction of a mixture of  $\text{LnCl}_3$  and  $\text{NaI}$  with two equiv. of  $\text{Na}[(\text{Me}_3\text{Si})_2\text{C}_5\text{H}_3]$  in THF.

Lanthanide (+)-neomenthylcyclopentadienyl complexes  $[\text{Cp}^R_2\text{Ln}(\mu\text{-Cl})_2]$  ( $\text{Ln} = \text{Sm}, \text{Yb}, \text{Y}, \text{Lu}$ ;  $\text{Cp}^R = (+)\text{-neomenthylcyclopentadienyl}$ ) and  $\text{Cp}^R\text{LnX}_2(\text{THF})_3$  ( $\text{X} = \text{Cl}, \text{Ln} = \text{Sm}, \text{Gd}, \text{Yb}, \text{Y}, \text{Lu}$ ;  $\text{X} = \text{I}, \text{Ln} = \text{Sm}, \text{Yb}$ ) are available from  $\text{LnCl}_3$  and the appropriate alkali metal (+)-neomenthylcyclopentadienyl complexes as chloride-bridged dimers.  $\text{Cp}^R\text{SmI}_2(\text{THF})_3$  is pseudo-octahedral with the two iodine atoms taking the trans positions.

$\text{Cp}^*_2\text{Y}(\mu\text{-Cl})\text{YCp}^*_2\text{Cl}$  reacts with oxygen-containing substrates to form monomeric adducts  $\text{Cp}^*_2\text{YCl}(\text{L})$  ( $\text{L} = \text{THF}$ , benzophenone, methylmethacrylate,  $\epsilon$ -caprolactone, hexamethylphosphoramide,  $\epsilon$ -caprolactam, 1-methyl-2-pyrrolidinone,  $N,N'$ -dimethylpropyleneurea). A bis-adduct,  $\text{Cp}^*_2\text{YCl}(\epsilon\text{-caprolactam})_2$  was isolated when an excess of  $\epsilon$ -caprolactam was used.<sup>67</sup>

Oxidation of  $\text{Cp}^*_2\text{Sm}$  with  $\text{AgBPh}_4$  in toluene yields  $[\text{Cp}^*_2\text{Sm}][\text{BPh}_4]$ , which in the solid state consists of a bent  $\text{Cp}^*_2\text{Sm}$  unit oriented toward two of the Ph rings of the  $[\text{BPh}_4]^-$  anion. Analogous Nd and Tm derivatives were prepared reacting  $\text{Cp}^*_2\text{Ln}(\eta^3\text{-CH}_2\text{CH=CH}_2)$  ( $\text{Ln} = \text{Nd}, \text{Tm}$ ) with  $[\text{Et}_3\text{NH}][\text{BPh}_4]$  in benzene.  $[(\text{C}_5\text{H}_4'\text{Bu})_2\text{Yb}(\text{THF})_2][\text{BPh}_4]$  has been synthesized from  $(\text{C}_5\text{H}_4'\text{Bu})_2\text{Yb}(\text{THF})_2$  and  $\text{AgBPh}_4$  followed by crystallization from THF. Related cationic organolanthanide compounds  $[(\text{C}_5\text{H}_4\text{R})_2\text{Sm}(\text{THF})_2][\text{BPh}_4]$  ( $\text{R} = \text{'Bu}, \text{SiMe}_3$ ),  $[\text{Pyr}^*_2\text{Sm}(\text{THF})][\text{BPh}_4]$  ( $\text{Pyr}^* = \text{NC}_4\text{H}_2'\text{Bu}_{2-2,5}$ ) (Figure 30a),  $[\text{Cp}^*_2\text{Ln}(\text{THF})_2][\text{BPh}_4]$  ( $\text{Ln} = \text{Y}, \text{Yb}$ ), and  $[(\text{C}_5\text{Me}_4\text{Et})_2\text{Ln}(\text{THF})_2][\text{BPh}_4]$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ) have been synthesized by oxidation of the divalent metallocenes

**Figure 30** (a)  $[\text{Pyr}^*_2\text{Sm}(\text{THF})][\text{BPh}_4]$ , (b)  $(\text{C}_4\text{Me}_4\text{P})_2\text{Lu}(\mu\text{-Cl})_2\text{Li}(\text{DME})$

with  $\text{AgBPh}_4$  or by protolysis of the lanthanide alkyls  $\text{Cp}^*_2\text{YMe}(\text{THF})$ ,  $\text{Cp}^*_2\text{YbCH}(\text{SiMe}_3)_2$ , and  $(\text{C}_5\text{Me}_4\text{Et})_2\text{-LnCH}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ), respectively, by  $[\text{Et}_3\text{NH}][\text{BPh}_4]$ . Bis(phospholyl) chloride complexes of Y and Lu can be prepared as DME (Figure 30b) or  $\text{Et}_2\text{O}$  adducts.

Phosphinoethyl substituted cyclopentadienyl complexes  $[\text{CpCH}_2\text{CH}_2\text{PR}_2]_2\text{LnX}$  ( $\text{Ln} = \text{Y}, \text{Lu}$ ;  $\text{R} = \text{Me}, \text{Cy}, \text{'Bu}, \text{Ph}$ ;  $\text{X} = \text{Cl}, \text{CF}_3\text{SO}_3$ ) show a distorted trigonal bipyramid with two axial phosphino groups and two equatorial cyclopentadienyl moieties, and the third equatorial site being occupied by the halide or triflate ligand (Figure 31).<sup>68</sup>

The lanthanum complex  $[(\text{MeOCH}_2\text{CH}_2\text{C}_5\text{H}_4)_2\text{La}(\mu\text{-Cl})_2]$  with ether-functionalized Cp ligands is a chlorine-bridged dimer. Optically active metallocene complexes of Y, Sm, and Lu containing cyclopentadienyl ligands with chiral nonracemic N- or O-substituted side chains, for example, (*S*)-(2-methoxypropyl)cyclopentadienyl, (*S*)-[2-(dimethylamino)propyl]cyclopentadienyl, and (*S*)-[2-(dimethylamino)-1-(phenylethyl)]cyclopentadienyl were prepared by reaction of the potassium salts of those cyclopentadienyl systems with the trichlorides of Y, Sm, and Lu in a 2:1 molar ratio:  $[(S)\text{-}\eta^5\text{:}\eta^1\text{-C}_5\text{H}_4(\text{CH}_2\text{CH}(\text{Me})\text{OMe})_2\text{LnCl}]$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ),  $\{[(S)\text{-}\eta^5\text{:}\eta^1\text{-C}_5\text{H}_4[\text{CH}_2\text{CH}(\text{Me})\text{NMe}_2]_2\text{LnCl}]$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ), and  $\{[(S)\text{-}\eta^5\text{:}\eta^1\text{-C}_5\text{H}_4[\text{CH}(\text{Ph})\text{CH}_2\text{NMe}_2]_2\text{LnCl}]$  ( $\text{Ln} = \text{Y}, \text{Sm}, \text{Lu}$ ). The mixed chiral sandwich complexes  $[(\eta^5\text{-Cp}^*)\{[(S)\text{-}\eta^5\text{:}\eta^1\text{-C}_5\text{H}_4[\text{CH}_2\text{CH}(\text{Me})\text{NMe}_2]_2\text{LnCl}]\}(\eta^5\text{-Cp}^*)]$  ( $\text{Ln} = \text{Y}, \text{Lu}$ ) and  $[(\eta^5\text{-Cp}^*)\{[(S)\text{-}\eta^5\text{:}\eta^1\text{-C}_5\text{H}_4[\text{CH}(\text{Ph})\text{CH}_2\text{NMe}_2]_2\text{LnCl}]\}(\eta^5\text{-Cp}^*)]$  ( $\text{Ln} = \text{Y}, \text{Lu}$ ) were prepared by successive reaction of  $\text{LnCl}_3$  with one equiv. of the potassium salt of the chiral nonracemic cyclopentadienyl ligand and one equiv. of  $\text{Cp}^*\text{Na}$ . In all the cases, the N- and O-donor functions are coordinated by the metals (Figure 32). An

**Figure 31**  $[(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{PR}_2)_2\text{LnOSO}_2\text{CF}_3]$

**Figure 32**  $[(\text{Cp}^*)\{[(S)\text{-}\eta^5\text{:}\eta^1\text{-C}_5\text{H}_4(\text{CHPhCH}_2\text{NMe}_2)_2\text{LnCl}]\}(\text{Cp}^*)]$

intramolecular coordination of the oxygen atom has also been found in the chiral lanthanocene iodides  $[(S)\text{-Cp}']_2\text{LnI}$  ( $\text{Ln} = \text{La}, \text{Sm}$ ;  $\text{Cp}' = \text{C}_5\text{H}_4\text{CH}_2\text{CHMeOCH}_2\text{Ph}$ ).

Lanthanide complexes with vinyl-substituted cyclopentadienyl ligands  $(\text{CH}_2=\text{CHC}_5\text{Me}_4)_2\text{Ln}(\mu\text{-Cl})_2\text{Li}(\text{Et}_2\text{O})_2$  ( $\text{Ln} = \text{Y}, \text{Sm}, \text{Lu}$ ),<sup>69</sup>  $[(\text{CH}_2=\text{CHCH}_2\text{CH}_2\text{C}_5\text{Me}_4)_2\text{Ln}(\mu\text{-Cl})_2]$  ( $\text{Ln} = \text{Y}, \text{Sm}, \text{Lu}$ ), and  $(\text{CH}_2=\text{CHCH}_2\text{CH}_2\text{C}_5\text{Me}_4)_2\text{-LnCl}(\text{THF})$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ) were prepared by exchange reactions with the lithium and sodium salts of the appropriate Cp-ligands.<sup>70</sup>  $(\text{CH}_2=\text{CHC}_5\text{Me}_4)_2\text{Sm}(\mu\text{-Cl})_2\text{Li}(\text{Et}_2\text{O})_2$  could be hydroborated with 9-BBN affording  $(\text{C}_8\text{H}_{14}\text{BCH}_2\text{-CH}_2\text{C}_5\text{Me}_4)_2\text{Sm}(\mu\text{-Cl})_2\text{Li}(\text{THF})_2$  (equation 19).<sup>69</sup>

(19)

Many bis(cyclopentadienyl)lanthanide oxides, hydroxides, alkoxides, and carboxylates have been prepared mainly by protonolysis of tris(cyclopentadienyl)lanthanides and bis(cyclopentadienyl)lanthanide alkyls, or by alkali halide abstraction from bis(cyclopentadienyl)lanthanide chlorides and water, alcohols, acids, or the corresponding alkali metal salts, respectively;<sup>6</sup> for example, dinuclear  $[\text{Cp}_2\text{Yb}(\mu\text{-OCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3)]_2$  (Figure 33a) and  $[\text{Cp}_2\text{Ln}(\mu\text{-OCH}_2\text{CH}_2\text{CHMe}_2)]_2$  ( $\text{Ln} = \text{Dy}, \text{Yb}$ ),  $[\text{Cp}_2\text{Ln}(\mu\text{-OPr})_2]$ , monomeric  $\text{Cp}_2\text{Ln}(\text{THF})(\text{OR}^F)$  [ $\text{Ln} = \text{Nd}, \text{Sm}, \text{Yb}$ ;  $\text{R}^F = 2,4,6\text{-tris(trifluoromethyl)phenyl}$ ] (Figure 33b),  $\text{Cp}_2\text{Yb}(\alpha\text{-naphthol})(\text{THF})$  were prepared by reacting of  $\text{Cp}_3\text{Ln}$  with respective alcohols or phenols. Monomeric organolanthanide acetates  $[(\text{C}_5\text{Me}_4'\text{Bu})_2\text{LnO}_2\text{CCH}_3]$  ( $\text{Ln} = \text{La}, \text{Lu}$ ) (Figure 33c) are prepared from  $[(\text{C}_5\text{Me}_4'\text{Bu})_2\text{LnCl}(\text{THF})]$  ( $\text{Ln} = \text{La}, \text{Lu}$ ) and  $\text{NaO}_2\text{CCH}_3$ .

Another approach to bis(cyclopentadienyl)lanthanide alkoxides is the cleavage of ethers by bis(cyclopentadienyl)lanthanide hydrides. Dialkyl ethers,  $\text{ROR}'$ , are cleaved by  $(\text{Cp}^*_2\text{LnH})_2$  ( $\text{Ln} = \text{Y}, \text{La}, \text{Ce}$ ) to form  $\text{Cp}^*_2\text{LnOR}$ ,  $\text{Cp}^*_2\text{LnOR}'$ ,  $\text{R}'\text{H}$ , and  $\text{RH}$ . The extent to which either of the C–O bonds of asymmetrically substituted dialkyl ethers  $\text{ROR}'$

**Figure 33** (a)  $[\text{Cp}_2\text{Yb}(\mu\text{-OCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3)]_2$ , (b)  $\text{Cp}_2\text{Ln}(\text{THF})(\text{OR}^F)$ , (c)  $[(\text{C}_5\text{Me}_4^t\text{Bu})_2\text{LnO}_2\text{CCH}_3]$

is attacked strongly depends on the alkyl substituents but is relatively insensitive to the nature of the metal. Ring opening is observed when THF or 1,4-dioxane reacted with hydrides to give  $\text{Cp}^*\text{YOBu}$  and  $(\text{Cp}^*\text{Y})_2(\mu\text{-OCH}_2\text{CH}_2\text{O})(\text{THF})_2$ , respectively. NMR studies in solution of the lanthanocene complexes containing a chiral alkoxide ligand, for example,  $[\text{Cp}_2\text{Ln}(\mu\text{-OCHRCHR}^1\text{NR}^2\text{R}^3)]_2$  ( $\text{R} = \text{H}$ ,  $\text{R}^1 = \text{Et}$ ,  $\text{R}^2$ ,  $\text{R}^3 = \text{Me}$  and  $\text{Ln} = \text{Pr}$ ,  $\text{Nd}$ ,  $\text{Sm}$ ,  $\text{Yb}$ ,  $\text{Lu}$ ) indicate an additional coordination of nitrogen to the lanthanide at room temperature for the  $\text{Pr}$ ,  $\text{Nd}$ , and  $\text{Sm}$  complexes (Figure 34).

Reaction of two equiv. of  $\text{Li}_2(\text{C}_5\text{R}_4\text{SiMe}_2\text{NCH}_2\text{CH}_2\text{X})$  ( $\text{C}_5\text{R}_4 = \text{C}_5\text{Me}_4$ ,  $\text{C}_5\text{H}_3^t\text{Bu}$ ;  $\text{X} = \text{OMe}$ ,  $\text{NMe}_2$ ) with  $\text{LnCl}_3$  ( $\text{Ln} = \text{Y}$ ,  $\text{Lu}$ ) yields  $\text{C}_2$ -symmetric complexes  $\text{Li}[(\eta^5:\eta^1\text{-C}_5\text{R}_4\text{SiMe}_2\text{NCH}_2\text{CH}_2\text{X})_2\text{Ln}]$  (Figure 35). In the case of  $\text{Li}[\text{Y}(\eta^5:\eta^1\text{-C}_5\text{H}_3^t\text{BuSiMe}_2\text{NCH}_2\text{CH}_2\text{X})_2]$ , a mixture of the two diastereomers in relative ratios depending on the reaction time are formed. The  $(R, S)$ -diastereomer is the kinetic

**Figure 34**  $[\text{Cp}_2\text{Sm}\{\mu\text{-OCHPhCH}_2\text{NMeCH}_2\text{Ph}\}]_2$

**Figure 36** (a)  $\text{Cp}^*_2\text{YN}(\text{SiHMe}_2)_2$ , (b)  $(\text{C}_5\text{H}_4\text{Me})_2\text{LnNC}_5\text{H}_{10}$ , (c)  $\text{Cp}_2\text{Ln}[\text{BuNCBuN}^t\text{Bu}]$

**Figure 35**  $\text{Li}[(\eta^5:\eta^1\text{-C}_5\text{H}_4\text{SiMe}_2\text{NCH}_2\text{CH}_2\text{OMe})_2\text{Ln}]$

product that rearranges to the thermodynamically preferred  $\text{C}_2$ -symmetric  $(R, R)$ -diastereomer in donor solvents such as THF.

Lanthanidocene silylamide complexes  $(\text{C}_5\text{HMe}_4)_2\text{YN}(\text{SiHMe}_2)_2$ ,  $\text{Cp}^*_2\text{YN}(\text{SiHMe}_2)_2$ , and  $(\text{C}_5\text{HPh}_4)_2\text{LaN}(\text{SiHMe}_2)_2$  were obtained by a silylamine elimination from  $\text{Ln}[\text{N}(\text{SiHMe}_2)_2]_3(\text{THF})_2$  ( $\text{Ln} = \text{Y}$ ,  $\text{La}$ ) and the respective cyclopentadienes. Deprotonation of tetraphenylcyclopentadiene was possible only in the case of  $\text{La}$ . The spectroscopic and structural data for these complexes revealed a strong agostic interaction (*see Agostic Bonding*) between the electron-deficient metal centers and the  $\text{SiH}$  moiety of the bis(dimethylsilyl)amide ligand (Figure 36a).<sup>71</sup> Amidolanthanidocenes  $(\text{C}_5\text{H}_4\text{Me})_2\text{LnNC}_5\text{H}_{10}$  ( $\text{Ln} = \text{Yb}$ ,  $\text{Er}$ ,  $\text{Y}$ ;  $\text{NC}_5\text{H}_{10} = \text{piperidine}$ ) (Figure 36b) were prepared reacting  $\text{LnCl}_3$  with  $\text{NaC}_5\text{H}_4\text{Me}$ , followed by treatment with  $\text{LiNC}_5\text{H}_{10}$ . The amidinate derivatives

$\text{Cp}_2\text{Ln}[\text{t-BuNC}(\text{Bu})\text{N}'\text{Bu}]$  ( $\text{Ln} = \text{Er}, \text{Y}, \text{Gd}$ ) (Figure 36c) were prepared by reaction of  $\text{Cp}_2\text{LnBu}$  (generated in situ) with *N,N'*-di-*tert*-butylcarbodiimide that proceeds via monoinsertion of carbodiimide into the  $\text{Ln}-\text{C}$   $\sigma$ -bond. The structurally characterized yttrium compound is a good catalyst for the cyclotrimerization of phenylisocyanate.<sup>72</sup>

Protonolysis of  $\text{Cp}_3\text{Ln}$  ( $\text{Ln} = \text{Dy}$  or  $\text{Yb}$ ) with thiols,  $\text{HSR}$  ( $\text{R} = \text{Pr}$  or  $\text{Bu}$ ) in THF yields dimeric thiolates  $[\text{Cp}_2\text{Ln}(\mu\text{-SR})_2]$  ( $\text{R} = \text{Pr}$ ;  $\text{Ln} = \text{Dy}$  or  $\text{Yb}$ ;  $\text{R} = \text{Bu}$ ;  $\text{Ln} = \text{Dy}$  or  $\text{Yb}$ ).  $[\text{Cp}_2\text{Yb}(\mu\text{-SBU})_2]$  has a planar  $\text{Yb}_2\text{S}_2$  unit with the Bu groups antipositioned relative to the  $\text{Yb}_2\text{S}_2$  ring (Figure 37a). Elemental Te readily inserts into the  $\text{Sc}-\text{C}$  bond of  $\text{Cp}^*\text{ScCH}_2\text{SiMe}_3$  and  $\text{Cp}^*\text{ScCH}_2\text{Ph}$  yielding the corresponding tellurates  $\text{Cp}^*\text{ScTeR}$  ( $\text{R} = \text{CH}_2\text{SiMe}_3$ ,  $\text{CH}_2\text{Ph}$ ). The phosphide complex  $\text{Cp}_2\text{Lu}[\mu\text{-PPh}_2]_2\text{Li}(\text{TMEDA})$  (Figure 37b) was obtained from  $\text{Ph}_2\text{PH}$  and  $\text{Cp}_2\text{Lu}(\mu\text{-Me})_2\text{Li}(\text{TMEDA})$ <sup>6</sup> and the reaction of  $[1,3\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_3]_2\text{YCl}$  with  $\text{KPHSi}'\text{Bu}_3$  yields  $[1,3\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_3]_2\text{YPHSi}'\text{Bu}_3$ .<sup>73</sup>

Bimetallic complexes  $\text{Cp}_2(\text{THF})\text{LuRu}(\text{CO})_2\text{Cp}$  (Figure 38a),  $[1,3\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_3]_2(\text{THF})\text{LuRu}(\text{CO})_2\text{Cp}$ , and  $\text{Cp}^*\text{LuRu}(\text{CO})_2\text{Cp}$  were prepared by reaction of  $\text{Na}[\text{CpRu}(\text{CO})_2]$  with the respective cyclopentadienyllutetium halides in THF. An X-ray structural study of  $(\text{THF})\text{Cp}_2\text{LuRu}(\text{CO})_2\text{Cp}$  revealed a direct  $\text{Lu}-\text{Ru}$  bond. Lanthanide–tungsten complexes  $\text{Cp}^*\text{Ln}(\text{C}_5\text{H}_4)\text{W}(\text{H})_2\text{Cp}$  ( $\text{Ln} = \text{Y}, \text{Sm}$ ) (Figure 38b) were prepared reacting  $(\text{Cp}^*\text{LnH})_2$  with  $\text{Cp}_2\text{WH}_2$ .

Bis(indenyl)lanthanide complexes are also described. According to X-ray crystallographic investigations  $(\text{C}_4\text{H}_7\text{OCH}_2\text{C}_9\text{H}_6)_2\text{LnCl}$  ( $\text{Ln} = \text{Nd}, \text{Sm}, \text{Dy}, \text{Ho}, \text{Er}, \text{Yb}$ ) (Figure 39) are unsolvated nine-coordinate monomeric complexes with a

Figure 39  $(\text{C}_4\text{H}_7\text{OCH}_2\text{C}_9\text{H}_6)_2\text{LnCl}$

trans arrangement of both the side arm and indenyl rings in the solid state.<sup>74</sup>

Similar structures were found for  $(\text{CH}_3\text{OCH}_2\text{CH}_2\text{C}_9\text{H}_6)_2\text{LnCl}$  ( $\text{Ln} = \text{Y}, \text{La}, \text{Nd}, \text{Gd}, \text{Ho}, \text{Lu}$ ). Neutral monomeric bis(indenyl) complexes containing alkenyl-functionalized ligands, for example,  $(\text{Ind}')_2\text{LnCl}(\text{THF})$  ( $\text{Ln} = \text{Gd}, \text{Er}$ ;  $\text{Ind}' = 1\text{-Allyl-2,4,7-trimethyl-1H-indene}$ ) and  $(\text{Ind}'')_2\text{LnCl}(\text{THF})$  [ $\text{Ln} = \text{Y}, \text{Lu}$ ;  $\text{Ind}'' = 1\text{-(3-buten-1-yl)-4,7-dimethyl-1H-indene}$ ] were prepared by reaction of  $\text{LnCl}_3$  with the lithium salts of the corresponding indenyl ligand. However, the trichlorides of the comparatively large Sm and La ions react with different molar amounts of  $\text{Ind}''\text{Li}$  in THF exclusively with formation of the tris(indenyl) complexes  $\text{Ind}''_3\text{Sm}$  and  $\text{Ind}''_3\text{La}(\mu\text{-Cl})\text{Li}(\text{Et}_2\text{O})_3$ , respectively. Single-crystal X-ray structural analyses show that the alkenyl groups of the indenyl side chains are not coordinated to the lanthanide atoms.<sup>64</sup>

### 7.3 Ansa-bis(cyclopentadienyl) Complexes

*ansa*-Lanthanidocene complexes are very important catalysts for a number of organic reactions such as hydrogenation (see *Hydrogenation*), hydrosilylation (see *Hydrosilylation*), -amination, and -phosphination of unsaturated compounds, as well as for the polymerization of olefins and for ring-opening polymerization of cyclic esters. The nature of the *ansa*-metallocene ligands impacts dramatically activity and stereoselectivity of the Ln-based catalysts.

*rac*-,  $C_1$ -, and *meso*-*ansa*-Metallocene complexes (see *Metallocene Complexes*) of Y and Sm, for example, *rac*- $\text{Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]_2\text{SmCl}_2\text{Li}(\text{THF})_2$ ,  $C_1$ - $\text{Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2][3,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]\text{SmCl}_2\text{Li}(\text{THF})_2$ ,  $C_1$ - $\text{Ph}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2][3,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]\text{SmCl}_2\text{Li}(\text{THF})_2$ , *meso*- $[1,2\text{-(Me}_2\text{Si)}(\text{Me}_2\text{SiOSiMe}_2)](4\text{-t-BuC}_5\text{H}_2)_2\text{SmCl}_2\text{Li}(\text{THF})_2$ , *rac*- $\text{Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]_2\text{YCl}_2\text{Li}(\text{THF})_2$ ,  $C_1$ - $\text{Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2][3,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]\text{YCl}_2\text{Li}(\text{THF})_2$ , *meso*- $[1,2\text{-(Me}_2\text{Si)}(\text{Me}_2\text{SiOSiMe}_2)](4\text{-Me}_3\text{SiC}_5\text{H}_2)_2\text{YCl}(\text{THF})$  were prepared and structurally characterized. Their structures differ with respect to the bridging group and the position of the substituents on the cyclopentadienyl rings. The alkyl complexes  $C_1$ - $\text{Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2][3,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]\text{SmCH}(\text{SiMe}_3)_2$  (Figure 40) and  $C_1$ - $\text{Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2][3,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]\text{YCH}(\text{SiMe}_3)_2$  polymerize ethylene, giving high molecular weight polyethylenes.<sup>75</sup>

Figure 37 (a)  $[\text{Cp}_2\text{Yb}(\mu\text{-SBU})_2]$ , (b)  $\text{Cp}_2\text{Lu}[\mu\text{-PPh}_2]_2\text{Li}(\text{TMEDA})$

Figure 38 (a)  $(\text{THF})\text{Cp}_2\text{LuRu}(\text{CO})_2\text{Cp}$ , (b)  $\text{Cp}^*\text{Sm}(\text{C}_5\text{H}_4)\text{W}(\text{H})_2\text{Cp}$

**Figure 40**  $C_1\text{-Me}_2\text{Si}[2,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2][3,4\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_2]\text{-SmCH(SiMe}_3)_2$

**Figure 41**  $\text{meso-Me}_2\text{Si(3-Me}_3\text{SiC}_5\text{H}_3)_2\text{YbBH}_4(\text{THF})$

The *ansa*-ytterbocene(III)  $\text{meso-Me}_2\text{Si(3-Me}_3\text{SiC}_5\text{H}_3)_2\text{-YbCl(THF)}$  undergoes desolvation during recrystallization from toluene yielding  $[\text{meso-Me}_2\text{Si(3-Me}_3\text{SiC}_5\text{H}_3)_2\text{Yb}(\mu_2\text{-Cl})]_2$ . Treatment with  $\text{LiBH}_4$  in  $\text{Et}_2\text{O}$  results in  $\text{meso-Me}_2\text{Si(3-Me}_3\text{SiC}_5\text{H}_3)_2\text{YbBH}_4(\text{THF})$  (Figure 41), in which ytterbium coordinates to three H atoms of the  $\text{BH}_4^-$  anion.

Reaction of  $\{\text{Me}_2\text{Si}[\text{C}_5\text{H}_2\text{-2,4-}^i\text{Pr}_2]_2\}\text{Li}_2$  with  $\text{ScCl}_3$  and  $\text{YCl}_3$  yields  $\text{rac-Me}_2\text{Si}[\text{C}_5\text{H}_2\text{-2,4-}^i\text{Pr}_2]_2\text{ScCl}[\text{LiCl(THF)}_2]$ ,  $\text{meso-Me}_2\text{Si}[\text{C}_5\text{H}_2\text{-2,4-}^i\text{Pr}_2]_2\text{Sc}(\mu_2\text{-Cl})_2$ ,  $\text{rac-Me}_2\text{Si}[\text{C}_5\text{H}_2\text{-2,4-}^i\text{Pr}_2]_2\text{YCl}[\text{LiCl(THF)}_2]$ , and  $\text{meso-Me}_2\text{Si}[\text{C}_5\text{H}_2\text{-2,4-}^i\text{Pr}_2]_2\text{Y}(\mu_2\text{-Cl})_2$  in approximately 3:1 racemic:meso ratios. Treatment of the Sc compounds with allylmagnesium bromide affords the allyl complexes *rac*- and *meso*- $\text{Me}_2\text{Si}[\text{C}_5\text{H}_2\text{-2,4-}^i\text{Pr}_2]_2\text{Sc}(\eta^3\text{-C}_3\text{H}_5)$ . Diastereomerically pure *rac*-compounds or pure *meso* dimers undergo spontaneous isomerization upon dissolution in  $\text{THF-d}_8$  with reversion back to a 3:1 racemic:meso ratio. The complexes  $\text{rac-Me}_2\text{C(3-}^t\text{BuC}_5\text{H}_3)_2\text{Yb}(\mu_2\text{-Cl})_2\text{Li(OEt)}_2$  and the monosolvate  $\text{meso-Me}_2\text{Si(3-Me}_3\text{SiC}_5\text{H}_3)_2\text{YbCl(THF)}$  were prepared reacting  $\text{Me}_2\text{E(3-Me}_3\text{EC}_5\text{H}_3)_2\text{Li}_2$  ( $\text{E} = \text{C, Si}$ ) with  $\text{YbCl}_3$ , respectively. The reaction between  $\text{Me}_2\text{C(3-}^t\text{BuC}_5\text{H}_3)_2\text{Li}_2$  and  $\text{YbI}_2$  in DME proceeds with solvent cleavage to form the dimeric methoxide complex  $[\text{meso-Me}_2\text{C(3-}^t\text{BuC}_5\text{H}_3)_2\text{Yb}(\mu_2\text{-OMe})]_2$  (Figure 42).

*ansa*-Metallocene complexes  $(R, S)\text{-Me}_2\text{Si}(^t\text{BuC}_5\text{H}_3)[(+)\text{-neo-Men-Cp}]\text{Ln}(\mu\text{-Cl})_2\text{Li(OEt)}_2$  ( $\text{Ln} = \text{Y, Lu}$ ;  $(+)\text{-neo-Men} = (+)\text{-neo-menthyl}$ ) were synthesized by reaction of the corresponding lanthanide trichlorides with the dilithium salt of the ligand and were isolated isomerically pure by crystallization from  $\text{Et}_2\text{O}$ . Alkylation of the  $(R, S)$ -epimers with  $\text{LiCH(SiMe}_3)_2$  proceeds with retention of configuration at the

**Figure 42**  $[\text{meso-Me}_2\text{C(3-}^t\text{BuC}_5\text{H}_3)_2\text{Yb}(\mu_2\text{-OMe})]_2$

**Figure 43**  $\{[(R, S)\text{-Me}_2\text{Si(C}_5\text{H}_3^t\text{Bu)(C}_5\text{H}_3\text{-}(+)\text{-neo-Men)}]\text{LuH}\}_2$

lanthanide center, affording chiral hydrocarbyl complexes in high yield. Reaction of the Lu-hydrocarbyl with  $\text{H}_2$  affords diastereomerically pure  $\{(R, S)\text{-Me}_2\text{Si}(^t\text{BuC}_5\text{H}_3)[(+)\text{-neo-Men-Cp}]\text{LuH}\}_2$  (Figure 43), an active catalyst for asymmetric olefin hydrogenation (see *Asymmetric Synthesis by Homogeneous Catalysis*).

Disiloxane-bridged metallocenes  $\{\text{O(Me}_2\text{SiC}_5\text{H}_4)_2\}\text{PrCl(THF)}$  and  $[\{\text{O(Me}_2\text{SiC}_5\text{H}_4)_2\}\text{YbCl}]_2$  (Figure 44a) were prepared from  $\text{LnCl}_3$  ( $\text{Ln} = \text{Pr or Yb}$ ) and  $\text{K}_2[\text{O(Me}_2\text{SiC}_5\text{H}_4)_2]$  in THF.  $[\text{Me}_2\text{Si(C}_5\text{H}_4)_2\text{Yb}(\mu\text{-Br})]_2$  and  $[\text{Me}_2\text{Si(C}_5\text{H}_4)_2\text{Yb}(\mu\text{-Cl})]_2$  are also dimers, like  $[\text{Me(R)Si(C}_5\text{H}_4)(\text{C}_5\text{Me}_4)\text{-LnCl}]_2$  ( $\text{R} = \text{Et, Ph}$ ;  $\text{Ln} = \text{Y, La, Sm, Lu}$ ) and  $[\text{Me(Et)Si(C}_5\text{H}_4)(\text{C}_5\text{Me}_4)\text{SmCl}]_2$ . Metallocenes with two cyclopentadienyl rings tethered by a 2,6-bis(methylene)pyridyl unit  $[\{2,6\text{-C}_5\text{H}_3\text{N(CH}_2\text{C}_5\text{H}_4)_2\}\text{Ln}(\mu\text{-O}_2\text{SOCF}_3)]_2$  ( $\text{Ln} = \text{Nd, Y, Yb}$ ) are also dimers with each triflate ligand bridging two Ln ions.<sup>76</sup>

$[\text{MeO(CH}_2)_5(\text{Me})\text{Si(C}_5\text{Me}_4)_2]\text{YCH(SiMe}_3)_2$ , containing a donor functionality in the Si bridge, exhibits low catalytic activity in such reactions as olefin hydrogenation, presumably because of the competition between the substrate (weak donor) and the donor functionality of the *ansa* ligand for the empty coordination site at the metal center. In contrast, for aminoalkene hydroamination/cyclization in which a strong amine donor is the substrate, catalytic activity is significantly enhanced while diastereoselectivity is essentially unchanged compared to nonfunctionalized analogs.

**Figure 44** (a)  $[\{O(Me_2SiC_5H_4)_2\}YbCl]_2$ , (b)  $[\{2,6-C_5H_3N(CH_2C_5H_4)_2\}Yb(\mu-O_2SOCF_3)]_2$

**Figure 45**  $rac\text{-}Me_2Si(2\text{-}Me\text{-}Benz\text{-}Ind)_2LnN(SiHMe_2)_2$

Brintzinger-type, indenyl-derived metallocene complexes  $rac\text{-}Me_2Si(2\text{-}Me\text{-}Benz\text{-}Ind)_2LnN(SiHMe_2)_2$  (Figure 45) and  $rac\text{-}Me_2Si(2\text{-}Me\text{-}C_9H_5)_2LnN(SiHMe_2)_2$  ( $Ln = Y, Lu$ ) have been prepared by silylamine elimination of  $Ln[N(SiHMe_2)_2]_3\text{-(THF)}_2$  and linked, substituted indene systems, and isolated in racemic yields as high as 72%.<sup>77</sup>

1,2-Bis(indenyl)ethane-derived *ansa*-lanthanidocenes [ $rac$ - and *meso*-( $CH_2$ )<sub>2</sub>( $\eta^5\text{-C}_9\text{H}_6\text{-1}$ )<sub>2</sub>LnCl][LiCl(Et<sub>2</sub>O)<sub>2</sub>] ( $Ln = Yb, Lu$ ) were synthesized from dilithiated 1,2-bis(indenyl)ethane with either  $YbCl_3$  or  $LuCl_3$  in THF followed by solvent exchange with Et<sub>2</sub>O. In the Yb case, the major diastereomer formed is *meso*, while in the case of Lu, the *rac* diastereomer predominated.

1,1'-(3-Oxapentamethylene)-bridged bis(indenyl) *ansa*-lanthanidocenes  $[O(CH_2CH_2C_9H_6)_2]LnCl(THF)$  ( $Ln = Y, Pr, Nd, Dy, Yb, Lu$ ) were obtained as a *rac*/*meso* mixture by the reaction of  $LnCl_3$  with  $O(CH_2CH_2C_9H_6)_2K_2$  in THF. Direct amidation or alkylation of the *rac*/*meso* mixtures in toluene provided solely pure racemic *ansa*-lanthanidocene amides  $[O(CH_2CH_2C_9H_6)_2]LnN(SiMe_3)_2$  ( $Ln = Y, Pr, Nd, Yb, Lu$ ) and pure racemic *ansa*-lanthanidocene hydrocarbyls  $[O(CH_2CH_2C_9H_6)_2]LnCH_2SiMe_3$  ( $Ln = Dy, Yb$ ), correspondingly. The amide and hydrocarbyl complexes are efficient single-component catalysts for MMA polymerization.<sup>78</sup>

$Me_2Si$ -bridged cyclopentadienyl/indenyl (donor-functionalized)-*ansa*-metallocenes  $\{Me_2Si(C_5H_2\text{-}3,5\text{-}iBuMe)[1\text{-}C_9H_5\text{-}3\text{-(CH}_2)_2NMe_2]\}LnCl$  ( $Ln = Y, Sm, Lu$ ) are

monomeric and solvent free with intramolecular coordination of the donor function to the metal as shown by X-ray crystallography of the Lu derivative (Figure 46).

A  $C_s$ -symmetric ytrocene complex, *ansa*- $Me_2Si(\eta^3\text{-Flu})(\eta^5\text{-C}_5Me_4)YCl_2Li(OEt)_2$  ( $Flu = C_{13}H_8$ , fluorenyl), was prepared from  $YCl_3$  and the dilithium salt of *ansa*- $Me_2Si(FluH)(C_5Me_4H)$ . Treatment with  $NaN(SiMe_3)_2$  yields the corresponding bis(trimethylsilyl)amide derivative *ansa*- $Me_2Si(Flu)(\eta^5\text{-C}_5Me_4)YN(SiMe_3)_2$  (Figure 47). In both complexes, the five-membered ring of the fluorenyl ligand is slipped from  $\eta^5$  toward an  $\eta^3$  coordination mode.

Lanthanide complexes with an unsymmetric cyclopentadienyl-fluorenyl ligand  $[Me_2C(\eta^5\text{-Flu})(\eta^5\text{-Cp})]Ln(\eta^5\text{-Cp})(FluH)CMe_2$  (Figure 48a) ( $Ln = Y, La, Nd$ ) were prepared by amine elimination from  $Ln[N(SiMe_3)_2]_3$  and  $(CpH\text{-}CMe_2\text{-}FluH)$ . These *ansa* complexes feature very 'open' Cp(centroid)–Ln–Flu(centroid) bite angles ( $Ln = La,$

**Figure 46**  $\{Me_2Si(C_5H_2\text{-}3,5\text{-}iBuMe)[1\text{-}C_9H_5\text{-}3\text{-(CH}_2)_2NMe_2]\}^-LuCl$

**Figure 47**  $ansa\text{-}Me_2Si(\eta^3\text{-Flu})(\eta^5\text{-C}_5Me_4)YN(SiMe_3)_2$

**Figure 48** (a)  $[\text{Me}_2\text{C}(\eta^5\text{-Flu})(\eta^5\text{-C}_5\text{H}_4)]\text{Ln}(\eta^5\text{-C}_5\text{H}_4)(\text{FluH})\text{CMe}_2$ , (b)  $\text{Me}_2\text{Si}(\text{OHF})(\text{C}_5\text{H}_3\text{R})\text{LnN}(\text{SiMe}_3)_2$

103°; Nd, 105°).<sup>79</sup> The related Lu complex  $[\text{Ph}_2\text{C}(\eta^5\text{-Flu})(\eta^5\text{-Cp})]\text{LuN}(\text{SiMe}_3)_2$  exhibits intramolecular β-C–Si agostic interaction with Lu. The complex was used as stereospecific catalyst in polymerization of MMA producing richly syndiotactic PMMA and in ring-opening polymerization of ε-caprolactone and δ-valerolactone producing polymers with moderate polydispersity.<sup>80</sup> Chiral C<sub>1</sub>-symmetric *ansa*-metallocenes  $\text{Me}_2\text{Si}(\text{OHF})(\text{C}_5\text{H}_3\text{R})\text{LnN}(\text{SiMe}_3)_2$  (Figure 48b) (OHF = η<sup>5</sup>-octahydrofluorenyl; R\* = (–)-menthyl; Ln = Sm, Y, Lu) exhibit catalytic activity for hydroamination/cyclization of aminoalkenes (≤67% enantioselectivities) and for the hydrophosphination/cyclization of phosphinoalkenes (≤96% diastereoselectivities).<sup>81</sup>

*ansa*-Metallocenes (η<sup>5</sup>:η<sup>5</sup>-C<sub>24</sub>H<sub>16</sub>)LnI(THF) (Figure 49) (Ln = Dy, Er, Tm, Lu) were prepared by in situ reactions of two equiv. of potassium acenaphthylenide K<sup>+</sup> C<sub>12</sub>H<sub>8</sub><sup>–</sup> with LnI<sub>3</sub>. Dimerization of two acenaphthylene radical anions produces a *rac-ansa*-metallocene structure with the Lu atom in a distorted tetrahedral geometry with two η<sup>5</sup>-coordinated five-membered rings of the acenaphthylene ligands, the iodine and the THF.<sup>82</sup>

Tris(peralkylcyclopentadienyl)samarium complexes containing two rings bridged by a Me<sub>2</sub>Si group were synthesized reacting SmI<sub>3</sub> first with Me<sub>2</sub>Si(C<sub>5</sub>Me<sub>4</sub>)<sub>2</sub> in THF followed by the reaction with KC<sub>5</sub>Me<sub>4</sub>R (R = Me, Et, <sup>n</sup>Pr, <sup>i</sup>Pr). When the second stage is carried out in toluene the solvent-free complexes Me<sub>2</sub>Si(C<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>-SmCp\* (Figure 50a), Me<sub>2</sub>Si(C<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>Sm(C<sub>5</sub>Me<sub>4</sub>Et), Me<sub>2</sub>-Si(C<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>Sm(C<sub>5</sub>Me<sub>4</sub><sup>n</sup>Pr), and Me<sub>2</sub>Si(C<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>Sm(C<sub>5</sub>Me<sub>4</sub>-<sup>i</sup>Pr) were isolated. In contrast to the reactivity of Cp\*<sub>3</sub>Sm,

**Figure 49** (η<sup>5</sup>:η<sup>5</sup>-C<sub>24</sub>H<sub>16</sub>)LuI(THF)

**Figure 50** (a)  $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)_2\text{SmCp}^*$ , (b)  $\text{Me}_4\text{C}_2(\text{C}_5\text{H}_4)_2\text{LuCp}(\text{THF})$

the complexes obtained do not cleave THF, do not reduce 1,3,5,7-C<sub>8</sub>H<sub>8</sub> or Ph<sub>3</sub>P=Se, and do not polymerize ethylene. Tris(cyclopentadienyl) compounds with two Cp rings linked by a tetramethylethano unit Me<sub>4</sub>C<sub>2</sub>(C<sub>5</sub>H<sub>4</sub>)<sub>2</sub>LnCp(THF) (Figure 50b) (Ln = Nd, Sm, Gd, Yb) were prepared by reaction of Me<sub>4</sub>C<sub>2</sub>(C<sub>5</sub>H<sub>4</sub>MgCl)<sub>2</sub> with LnCl<sub>3</sub> followed by CpNa in THF.

#### 7.4 Mono(cyclopentadienyl) Complexes

Monomeric half-sandwich complexes (*see Half-sandwich Complexes*) bearing double-N-functionalized cyclopentadienyl ligands  $[\text{C}_5\text{H}_3(\text{CH}_2\text{CH}_2\text{NMe}_2)_2\text{-1,2}]\text{LaI}_2(\text{THF})$  (Figure 51a) and  $[\text{C}_5\text{H}_3(\text{CH}_2\text{CH}_2\text{NMe}_2)_2\text{-1,3}]\text{LaI}_2(\text{THF})$  (Figure 51b), were prepared reacting LaI<sub>3</sub> with K[1,2-C<sub>5</sub>H<sub>3</sub>(CH<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub>)<sub>2</sub>] and K[1,3-C<sub>5</sub>H<sub>3</sub>(CH<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub>)<sub>2</sub>].

**Figure 51** (a)  $[\text{C}_5\text{H}_3(\text{CH}_2\text{CH}_2\text{NMe}_2)_2\text{-1,2}]\text{LaI}_2(\text{THF})$ , (b)  $[\text{C}_5\text{H}_3(\text{CH}_2\text{CH}_2\text{NMe}_2)_2\text{-1,3}]\text{LaI}_2(\text{THF})$

In both complexes, the La atoms have a distorted octahedral geometry. However, different coordination requirements of the tridentate 1,2- and 1,3-substituted cyclopentadienyl ligands cause different positions of the iodine atoms and the THF molecule around the metal.<sup>83</sup>

The (+)-neomenthylcyclopentadienyllanthanide complexes  $\text{Cp}^R\text{LnX}_2(\text{THF})_3$  [ $\text{X} = \text{Cl}$ ,  $\text{Ln} = \text{Sm}$ ,  $\text{Gd}$ ,  $\text{Yb}$ ,  $\text{Y}$ ,  $\text{Lu}$ ;  $\text{X} = \text{I}$ ,  $\text{Ln} = \text{Sm}$ ,  $\text{Yb}$ ;  $\text{Cp}^R = (+)\text{-neomenthylcyclopentadienyl}$ ] were prepared by reaction of  $\text{LnCl}_3$  with appropriate alkali metal cyclopentadienyl derivatives. In the solid state, the monomeric  $\text{Cp}^R\text{SmI}_2(\text{THF})_3$  adopts a pseudo-octahedral geometry with the two iodine atoms taking trans positions. A similar structure is found for  $(\text{Ind})\text{GdCl}_2(\text{THF})_3$ .

Half-sandwich cyclopentadienyl lanthanide complexes  $\{[(\eta^5\text{-C}_5\text{H}_4^t\text{Bu})\text{Ln}(\text{THF})_2(\mu_2\text{-Cl})_2(\mu_3\text{-Cl})_3\text{Na}(\text{THF}))_n$  ( $\text{Ln} = \text{Nd}$ ,  $\text{Sm}$ ,  $\text{Gd}$ ,  $\text{Yb}$ ) are available from the reaction of  $\text{LnCl}_3$  with  $\text{NaC}_5\text{H}_4^t\text{Bu}$  in THF. The Sm complex reacts with  $\text{Na}_2\text{Se}_5$  yielding hexanuclear  $[\text{Na}(\text{THF})_6]_2[(\eta^5\text{-C}_5\text{H}_4^t\text{Bu})_6\text{Sm}_6(\mu_6\text{-Se})(\mu\text{-Se}_2)_6]$  (Figure 52).<sup>84</sup> Earlier described clusters containing monocyclopentadienylsamarium units are  $[\text{Cp}_{12}\text{Sm}_{12}(\mu_3\text{-Cl})_{24}]$ ,  $[(\text{Cp}^*\text{Sm})_6\text{Se}_{11}]$ , and  $[(\text{Cp}^*\text{Sm})_6\text{Se}_{11}]$ .

The reaction of  $\text{Sm}(\text{OAr})_3(\text{THF})$  ( $\text{Ar} = 2,6\text{-}^t\text{Bu}_2\text{C}_6\text{H}_3$ ) with one equiv. of  $\text{LiCp}^*$  produces  $\text{Cp}^*\text{Sm}(\text{OAr})_2(\text{THF})$ , which reveals a three-legged piano stool (*see Piano Stool Structure*) geometry. The monocyclopentadienyl yttrium complex containing a diamide ligand,  $\text{CpY}\{\text{ArN}(\text{CH}_2)_3\text{NAr}\}(\text{THF})$  ( $\text{Ar} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$ ) (Figure 53)

**Figure 52** Structure of  $[\text{Na}(\text{THF})_6]_2[(\eta^5\text{-C}_5\text{H}_4^t\text{Bu})_6\text{Sm}_6(\mu_6\text{-Se})(\mu\text{-Se}_2)_6]$  (Cp ligands are omitted)

**Figure 53**  $\text{CpY}\{\text{ArN}(\text{CH}_2)_3\text{NAr}\}(\text{THF})$

was obtained from alkali metal salts of the ligand and cyclopentadiene.<sup>85</sup>

Besides the *ansa*-metallocene complexes with so-called *constrained geometry ligands* are used as effective catalysts in a number of important organic reactions. Constrained geometry ligands combine alkoxido-, amido- or other functions attached to the cyclopentadienyl ring. A variety of linkers between the Cp ring and the covalently bonded function, which both rigidly coordinate to the metal, enables the shaping of the free coordination sphere of the metal thus permitting a fine tuning of complex reactivity.<sup>25,86</sup> For alkyl lanthanide complexes supported by constrained geometry ligands see paragraph 2.3.

Reaction of  $\text{Y}[\text{N}(\text{SiMe}_3)_2]_3$  with  $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4\text{H})(\text{N}(\text{H})\text{-}^t\text{Bu})$  at  $100^\circ\text{C}$  results in elimination of 2 equiv. of  $\text{HN}(\text{SiMe}_3)_2$  and attachment of the Cp-amido ligand to yttrium. Later this synthetic approach was used for the preparation of related amide and alkyl complexes, for example,  $[\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)(\text{N}^t\text{Bu})]\text{LnE}(\text{SiMe}_3)_2$  ( $\text{Ln} = \text{Sm}$ ,  $\text{Nd}$ ,  $\text{Yb}$ ,  $\text{Lu}$ ;  $\text{E} = \text{CH}$ ,  $\text{N}$ ) (Figure 54). They are significantly more active than the corresponding complexes  $\text{Cp}^*_2\text{LnE}(\text{SiMe}_3)_2$  as precatalysts for aminoalkene hydroamination/cyclization.

Yttrium alkyl complexes  $\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)(\eta^1\text{-NCMe}_2\text{-R})\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ ) and  $\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\eta^1\text{-N}^t\text{Bu})\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})$  were prepared in high yields from  $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  and amino-functionalized cyclopentadienes or indene, respectively. According to single-crystal X-ray diffraction,  $\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)(\eta^1\text{-NCMe}_2\text{Et})\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})$  has a three-legged piano stool geometry. Reaction of  $\text{Y}(\text{CH}_2\text{SiMe}_3)_3(\text{THF})_2$  with the tridentate linked amido-cyclopentadienyl ligands  $(\text{C}_5\text{Me}_4\text{H})\text{SiMe}_2\text{NHR}$  ( $\text{R} = \text{CH}_2\text{CH}_2\text{OMe}$ ,  $\text{CH}_2\text{CH}_2\text{NMe}_2$ ,  $\text{CH}_2\text{CH}_2\text{CH}_2\text{OMe}$ ,  $\text{CMe}_2\text{-CH}_2\text{OMe}$ ), which contain an additional donor functionality, results in the cleavage of the silicon-cyclopentadienyl bond and formation of  $(\text{C}_5\text{Me}_4\text{H})[\text{N}(\text{SiMe}_2\text{CH}_2\text{SiMe}_3)(\text{R})]\text{Y}(\text{CH}_2\text{SiMe}_3)(\text{THF})_n$  ( $n = 0, 1$ ) (Figure 55a). The dimeric hydrido complexes  $[\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\eta^1\text{-NCMe}_2\text{R})\text{Y}(\mu\text{-H})(\text{THF})]_2$  were synthesized by hydrogenolysis of the corresponding alkyl derivatives. They polymerize ethylene, whereas styrene and 1-hexene were cleanly converted into the monoinsertion products. Styrene derivatives react with the hydrido complexes to give, for example,  $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\eta^1\text{-NCMe}_2\text{R})\text{Y}(\text{CH}_2\text{C}_6\text{H}_4^t\text{Bu})(\text{THF})$  (Figure 55b). The insertion product of 1-hexene initiates the polymerization of styrene

**Figure 54**  $[\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)(\text{N}^t\text{Bu})]\text{YbN}(\text{SiMe}_3)_2$

**Figure 55** (a)  $(C_5Me_4H)\{N(SiMe_2CH_2SiMe_3)(t-Bu)\}Y(CH_2SiMe_3)(THF)_n$ , (b)  $Me_2Si(C_5Me_4)(\eta^1-NCMe_2Et)Y(CH_2C_6H_4^tBu)(THF)$

yielding atactic polystyrene with a narrow molecular weight distribution and microstructures enriched in syndiotacticity.<sup>87</sup>

Oxirane-ring opening of butylglycidyl ether with cyclopentadienylsodium or indenylsodium affords cyclopentadienyl- and indenyl-substituted alcohols  $RHCH_2CH(OH)CH_2OBu$  ( $R = C_5H_4$  or  $3-C_9H_6$ ), which deprotonate with  $Ln[N(SiMe_3)_2]_3$  to give corresponding lanthanide complexes  $\{[(\eta^5-R)CH_2CH(\mu_2-\eta^1-O)CH_2OBu]LnN(SiMe_3)_2\}_2$  ( $R = C_5H_4$ ,  $Ln = La, Pr, Er, Lu$ ;  $R = 1-C_9H_6$ ,  $Ln = La$ ) (Figure 56). The coordination spheres of the metal atoms in these complexes involve simultaneously the  $\eta^5$ -cyclopentadienyl (indenyl), bridging alkoxide, and terminal amide ligands.<sup>88</sup>

Deprotonation of a  $CpH/OH$  ligand with  $Y[N(SiMe_3)_2]_3$  yields the neutral chloride complex  $[\eta^5:\eta^1-C_5H_4CH_2\{3,5-C_6H_3(CF_3)_2\}_2CO]_2YCl(THF)$ , which is further converted to amide, alkoxide, or alkyl derivatives by reacting with one equiv. of  $NaN(SiMe_3)_2$ ,  $LiOC_6H_3^tBu_{2,6}$ , and  $LiCH(SiMe_3)_2$  respectively. The molecular structure of

**Figure 56**  $\{[\eta^5-C_5H_4CH_2CH(\mu_2-\eta^1-O)CH_2OBu]La-N(SiMe_3)_2\}_2$

**Figure 58** (a)  $[Me_2Si(C_5Me_4)(PAr)Sm(THF)]_2(\mu-\eta^2-OCPh_2)$ , (b)  $[Me_2Si(C_5Me_4)(PAr)Sm(\mu-I)(THF)]_2$

**Figure 57**  $[\eta^5:\eta^1-C_5H_4CH_2\{3,5-C_6H_3(CF_3)_2\}_2CO]Y(OC_6H_3^tBu_2)(THF)_2$

the amide<sup>89</sup> and phenoxide (Figure 57) derivatives were established by X-ray crystallography.<sup>90</sup>

Lanthanide(II) complexes  $Me_2Si(C_5Me_4)(PAr)Ln(THF)_3$  ( $Ln = Sm, Yb$ ;  $Ar = C_6H_2^tBu_{3-2,4,6}$ ) were prepared by reaction of  $SmI_2$  and  $YbI_2$ , respectively, with  $K_2[Me_2Si(C_5Me_4)(PAr)]$ . Oxidation of the  $Sm$  complex with benzophenone or  $ICH_2CH_2I$  in THF afforded  $[Me_2Si(C_5Me_4)(PAr)Sm(THF)]_2(\mu-\eta^2-OCPh_2)$  (Figure 58a) and  $[Me_2Si(C_5Me_4)(PAr)Sm(\mu-I)(THF)]_2$  (Figure 58b), respectively.<sup>91</sup>

## 7.5 Lanthanide Complexes with Carboranyl Ligands

A number of organolanthanide complexes with carboranes either bonded to the lanthanide metals via one carbon atom or with an open side as Cp analogs have been

described (see **Boron, Metallocarboranes**). The dimethylsilyl bridged carboranyl/indenyl ligand  $\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})$  can be reduced to the monoanion  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]^-$ , the dianion  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{10})]^{2-}$ , and the trianion  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_9)]^{3-}$  by treatment with NaH or K in THF. Reaction of  $\text{LnCl}_3$  with one equiv. of  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Na}$  in THF yields  $[\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{LnCl}_2(\text{THF})_3$  ( $\text{Ln} = \text{Nd}, \text{Er}$ ). They further react with another equiv. of  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Na}$  to afford  $[\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]_2\text{LnCl}(\text{THF})_2$  ( $\text{Ln} = \text{Ce}, \text{Nd}, \text{Sm}, \text{Er}$ ).  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{K}_3$  reacts with  $\text{ErCl}_3$  forming  $\eta^5:\eta^6\text{-}[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Er}(\text{THF})_2$  (Figure 59).

The related  $\text{Me}_2\text{C}$ -bridged ligand  $\text{Me}_2\text{C}(\text{C}_9\text{H}_7)(\text{C}_2\text{B}_{10}\text{H}_{11})$  can be converted only into the monoanion  $[\text{Me}_2\text{C}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]^-$  and the dianion  $[\text{Me}_2\text{C}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{10})]^{2-}$  by treatment with one or two equiv. of BuLi, respectively. Reaction of  $\text{LnCl}_3$  with one or two equiv. of the monoanionic salt yields  $[\text{Me}_2\text{C}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{GdCl}_2(\text{THF})_2$

Figure 59  $[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Er}(\text{THF})_2$

Figure 60  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{11})]_3\text{Sm}$

and  $[\text{Me}_2\text{C}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]_2\text{LnCl}(\text{THF})(\text{OEt}_2)$ , respectively ( $\text{Ln} = \text{Y}, \text{Yb}$ ).<sup>92</sup> Using  $[\text{Me}_2\text{C}(\text{C}_5\text{H}_5)(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Na}$ , neutral  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{11})]_3\text{Sm}$  (Figure 60) can be isolated besides  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{SmCl}_2(\text{THF})_3$  and  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{11})]_2\text{SmCl}(\text{THF})_2$ .<sup>93</sup>

The first organolanthanide compound containing an  $\eta^7$ -carboranyl ligand,  $[\{[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\eta^7\text{-C}_2\text{B}_{10}\text{H}_{11})]\text{Er}\}_2\text{-}\{\text{Na}_4(\text{THF})_9\}]_n$  (Figure 61), was prepared by treatment of  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{ErCl}_2(\text{THF})_3$  or  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\eta^6\text{-C}_2\text{B}_{10}\text{H}_{11})]\text{Er}(\text{THF})_2$  with excess of Na in THF.

Silylamine elimination reactions of the boron-bridged ligand  $^i\text{Pr}_2\text{NB}(\text{C}_9\text{H}_7)(\text{C}_2\text{B}_{10}\text{H}_{11})$  incorporating indenyl and carboranyl moieties and  $\text{Ln}[\text{N}(\text{SiHMe}_2)_2]_3$  resulted in the formation of  $[\text{Pr}_2\text{NB}(\eta^5\text{-C}_9\text{H}_6)(\eta^1\text{-C}_2\text{B}_{10}\text{H}_{10})]\text{Ln}-\text{N}(\text{SiHMe}_2)_2(\text{THF})_2$  ( $\text{Ln} = \text{Nd}, \text{Er}, \text{Y}$ ) (Figure 62).<sup>94</sup>

Treatment of 1,2-( $\text{PhCH}_2$ )<sub>2</sub>-1,2- $\text{C}_2\text{B}_{10}\text{H}_{10}$  with excess Na or Li in THF followed by reaction with  $\text{LnCl}_3$  in the presence of excess alkali metal gave the 13-vertex closo-metallacarboranes  $\{[(\text{PhCH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}]\text{Ln}(\text{THF})\}_2\text{-}\{\text{Na}(\text{THF})_3\}_2$  ( $\text{Ln} = \text{Dy}, \text{Y}, \text{Er}$ ) or  $\{[(\text{PhCH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}]\text{Ln}(\text{THF})\}_2[\text{Li}(\text{THF})_4]_2$  (Figure 63) ( $\text{Ln} = \text{Y}, \text{Er}$ ), respectively. The yttrium complexes were the first examples of  $d^0$  metallocarboranes incorporating an  $\eta^7$ -carboranyl ligand. Density functional calculations indicate that the metal-carborane bonding is well delocalized and can be described as

Figure 61 Structure of the dianionic fragment  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)(\eta^7\text{-C}_2\text{B}_{10}\text{H}_{11})]\text{Er}$

Figure 62  $[\text{Pr}_2\text{NB}(\eta^5\text{-C}_9\text{H}_6)(\eta^1\text{-C}_2\text{B}_{10}\text{H}_{10})]\text{LnN}(\text{SiHMe}_2)_2(\text{THF})_2$

**Figure 63**  $[(\text{PhCH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}]\text{Y}(\text{THF})_2[\text{Li}(\text{THF})_4]_2$

the orbital interactions between the metal's five d orbitals and the cage's five symmetry-adapted frontier orbitals. It is anticipated that only the  $d^0/f^n$  transition metal ion with the proper size is capable of being  $\eta^7$ -bound to an *arachno*-carboranyl ligand.<sup>95</sup>

Treatment of the sodium salt of the 'carbons-adjacent' *nido*-carborane anion  $[\{\mu\text{-}1,2\text{-}[o\text{-C}_6\text{H}_4(\text{CH}_2)_2]\text{-}1,2\text{-C}_2\text{B}_{10}\text{H}_{10}\}_2\text{Na}_4(\text{THF})_6]_n$  with two equiv. of  $\text{LnCl}_3$  gave  $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-C}_6\text{H}_4(\text{CH}_2)_2]\text{-}1,2\text{-C}_2\text{B}_{10}\text{H}_{10}\}]\text{LnCl}(\text{THF})_3$  ( $\text{Ln} = \text{Nd, Er, Y}$ ). Further reactions with  $\text{NaBH}_4$  and  $\text{NaC}_5\text{H}_5$  resulted in  $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-C}_6\text{H}_4(\text{CH}_2)_2]\text{-}1,2\text{-C}_2\text{B}_{10}\text{H}_{10}\}]\text{Nd}[(\mu\text{-H})_3\text{-BH}](\text{THF})_3$  (Figure 64) and  $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-C}_6\text{H}_4(\text{CH}_2)_2]\text{-}1,2\text{-C}_2\text{B}_{10}\text{H}_{10}\}]\text{Y}(\eta^5\text{-C}_5\text{H}_5)(\text{THF})$ , respectively.<sup>96</sup>

The erbacarborane sandwich complex  $2,2',4,4'\text{-(Me}_3\text{Si)}_4\text{-}3,6'\text{-}[(\mu\text{-H})_2\text{K}(\text{THF})_2]\text{-}1,1'\text{-}commo\text{-Er}(\eta^5\text{-}2,4\text{-C}_2\text{B}_4\text{H}_4)_2$  (Figure 65) results from the reaction of  $1,2\text{-(Me}_3\text{Si)}_2\text{-}1,2\text{-C}_2\text{B}_4\text{H}_4$  with  $\text{ErCl}_3$  and potassium in a 2:1:4 molar ratio, in the absence of an outside electron-transfer agent.<sup>97</sup>

**Figure 64**  $[\eta^6\text{-}\{\mu\text{-}1,2\text{-}[o\text{-C}_6\text{H}_4(\text{CH}_2)_2]\text{-}1,2\text{-C}_2\text{B}_{10}\text{H}_{10}\}]\text{Nd}[(\mu\text{-H})_3\text{BH}](\text{THF})_3$

**Figure 65**  $2,2',4,4'\text{-(Me}_3\text{Si)}_4\text{-}3,6'\text{-}[(\mu\text{-H})_2\text{K}(\text{THF})_2]\text{-}1,1'\text{-}commo\text{-Er}(\eta^5\text{-}2,4\text{-C}_2\text{B}_4\text{H}_4)_2$

## 8 ARENE COMPLEXES

A comprehensive review covers the whole literature on arene complexes of the rare earth elements up to 2002.<sup>98</sup>

### 8.1 Complexes with Neutral Arene Ligands

Chloroaluminate complexes of the general formula  $\text{Ln}(\eta^6\text{-Arene})(\eta^2\text{-AlCl}_4)_3$  (equation 20) were prepared by reacting  $\text{AlCl}_3$  with  $\text{LnCl}_3$  in the corresponding aromatic solvent. In some cases, the reactions proceed only with addition of aluminum powder. The first compound of this type,  $\text{Sm}(\eta^6\text{-C}_6\text{Me}_6)(\text{AlCl}_4)_3$ , was reported in 1986.

| Arene             | Lanthanide                               |
|-------------------|------------------------------------------|
| Benzene           | La, Nd, Sm, Yb                           |
| Toluene           | Sm, Nd, Gd ( $[\text{AlBr}_4]\text{-}$ ) |
| <i>m</i> -Xylene  | Pr, Er                                   |
| Mesitylene        | Nd                                       |
| Hexamethylbenzene | Nd, Sm, Gd, Yb                           |

The molecular structure of  $\text{Sm}(\eta^6\text{-C}_6\text{Me}_6)(\text{AlCl}_4)_3$  shows a distorted pentagonal bipyramid with the  $\eta^6$ -arene occupying an apical site.  $\text{Nd}(\eta^6\text{-C}_6\text{H}_5\text{Me})(\text{AlCl}_3\text{Me})_3$  has been prepared by reaction of  $\text{Nd}(\eta^6\text{-C}_6\text{H}_5\text{Me})(\text{AlCl}_4)_3$  with  $\text{AlMe}_3$ .  $(\eta^6\text{-C}_6\text{H}_6)\text{Sm}(\text{AlCl}_4)_2$  and  $(\eta^6\text{-C}_6\text{H}_3\text{Me}_3)\text{Sm}(\text{AlCl}_4)_2$  were prepared by reduction of  $\text{SmCl}_3$  with  $\text{Na/Hg}$  in the presence of  $\text{AlCl}_3$  and the corresponding aromatic ligand. Single-crystal X-ray diffraction showed the Sm atom pentagonal-bipyramidal coordinated by the  $\pi$ -aromatic ligand and six Cl atoms. Analogous Yb(II) chloroaluminates  $(\eta^6\text{-C}_6\text{H}_6)_2\text{Yb}(\text{AlCl}_4)_2$  and  $(\eta^6\text{-C}_6\text{H}_3\text{Me}_3)\text{Yb}(\text{AlCl}_4)_2$  have been synthesized by the same synthetic approach.

Abstraction of methide from the  $\beta$ -diketiminato supported organoscandium complex  $[\text{LScMe}_2]_2$  using  $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$  in arene solvents gives solvent separated ion pairs in which the arenes ( $\text{C}_6\text{H}_5\text{Br}$ ,  $\text{C}_6\text{H}_6$ ,  $\text{C}_6\text{H}_5\text{Me}$ ,  $1,3,5\text{-Me}_3\text{C}_6\text{H}_3$ ) are coordinated to the cationic scandium center in an  $\eta^6$ -fashion. Although the aromatic fragment in the bromobenzene

**Figure 66**  $[\text{LSc}(\text{Me})(\text{C}_6\text{H}_5\text{Br})][\text{B}(\text{C}_6\text{F}_5)_4]$  (Diip = 2,6-diisopropylphenyl, R = Br)

derivative  $[\text{LSc}(\text{Me})(\text{C}_6\text{H}_5\text{Br})][\text{B}(\text{C}_6\text{F}_5)_4]$  (Figure 66) is  $\eta^6$ -bonded, steric interactions invoke significant ring tilting.<sup>99</sup>

The reaction of  $\text{Nd}[\text{N}(\text{SiMe}_3)_2]_3$  with  $(\text{C}_6\text{F}_5)_2\text{NH}$  in PhMe yields  $[(\eta\text{-PhMe})\text{Nd}[\text{N}(\text{C}_6\text{F}_5)_2]_3]$  in which the Nd atom is  $\eta^6$ -bonded to a toluene solvent molecule.

$\eta^6$ -Arene coordination between lanthanide ions and phenyl groups of certain phenolate and thiolate ligands have been detected in some unsolvated lanthanide complexes, for example,  $\text{Ln}(\text{SAr})_2$  (Ln = Eu, Yb; Ar = 2,6-Trip<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; Trip = 2,4,6-*i*-Pr<sub>3</sub>C<sub>6</sub>H<sub>2</sub>),  $[\text{Eu}_2(\text{OAr})(\mu\text{-OAr})_3]$  (OAr = 2,6-diphenylphenolate), and  $\text{Ln}_2(\text{O-2,6-(Me}_2\text{CH)}_2\text{C}_6\text{H}_3)_6$  (Ln = Nd, Sm, Er),  $[\text{Sc}(\text{OArH})_3]$  (OAr = 2,6-diphenylphenolate).<sup>100</sup> The reactions of the lanthanide metal powders with  $\text{Hg}(\text{C}_6\text{F}_5)_2$  and 2,6-diphenylphenol in THF afford the lanthanide(III) phenoxides  $\text{Ln}(\text{2,6-OC}_6\text{H}_3\text{Ph}_2)_3$  (Ln = Nd, Sm, Er, Yb, Lu) and the corresponding THF solvates. In the unsolvated compound  $\text{Yb}(\text{2,6-OC}_6\text{H}_3\text{Ph}_2)_3$ , one phenyl substituent is in a geometrically favorable position that allows this ring to engage in a novel  $\pi$ -interaction with the central ytterbium atom (Figure 67).

Reaction of 3 equiv. of 2,6-diisopropylaniline with  $\text{Sm}[\text{N}(\text{SiMe}_3)_2]_3$  affords dimeric  $[\text{Sm}(\text{NHAr})_3]_2$ , in which each metal center is engaged in an  $\eta^6$ -arene interaction with the aryl ring of an amide ligand attached to an adjacent samarium. IR spectroscopy indicates that the  $\pi$ -arene interactions are maintained in solution.<sup>101</sup>

## 8.2 Complexes with Anionic Arenes and Heterocyclic Aromatic Ligands

Treatment of  $\text{Cp}^*\text{Ln}$  [ $\text{Cp}^* = 1,3\text{-bis}(\text{trimethylsilyl})\text{cyclopentadienide}$ ; Ln = La, Ce, Pr, Nd] with 2 equiv. of 18-crown-6 and 2 equiv. of potassium in benzene affords lanthanide complexes with  $\text{C}_6\text{H}_6$  dianions. The molecular

**Figure 67**  $\text{Yb}(\text{2,6-OC}_6\text{H}_3\text{Ph}_2)_3$  (Ar = 2,6-OC<sub>6</sub>H<sub>3</sub>Ph<sub>2</sub>)

**Figure 68**  $[\text{K}([18\text{-crown-6})][\text{La}\{\eta^5\text{-C}_5\text{H}_3(\text{SiMe}_3)_2\text{-1,3}\}_2(\text{C}_6\text{H}_6)]$

structure of the isomorphous La, Ce, and Nd salts  $[\text{K}([18\text{-crown-6})][\text{Ln}\{\eta^5\text{-C}_5\text{H}_3(\text{SiMe}_3)_2\text{-1,3}\}_2(\text{C}_6\text{H}_6)]$  (Ln = La, Ce, Pr, Nd) shows a tight ion pair with a boat-shaped  $\text{C}_6\text{H}_6$  dianion bridging the K and the Ln atoms (Figure 68).

Phenylation of Y and Ho complexes  $(\text{LnL})_2(\mu\text{-Cl})_2$  (Ln = Y, Ho; L = *syn*-PhP[CH<sub>2</sub>(SiMe<sub>2</sub>)N(SiMe<sub>2</sub>)CH<sub>2</sub>]<sub>2</sub>-PPh) with PhLi in Et<sub>2</sub>O/toluene results with coupling of two phenyl anions in binuclear compounds  $[(\text{L})\text{Ln}]_2(\mu\text{-}\eta^6\text{:}\eta^6\text{-Ph}_2)$  with a bridging diphenyl dianion. In these complexes, the Ln atoms are bonded to opposite sides of different rings of the biphenyl ligand, which retains its planarity (Figure 69).

In contrast,  $(\text{YbL})_2(\mu\text{-Cl})_2$  reacts with PhLi yielding the paramagnetic monophenyl compound (L)YbPh.<sup>102</sup> Reduction of  $(\text{L})\text{LnCl}(\text{THF})$  (Ln = Y, Lu; L = *syn*-PhP[CH<sub>2</sub>(SiMe<sub>2</sub>)N(SiMe<sub>2</sub>)CH<sub>2</sub>]<sub>2</sub>-PPh) with KC<sub>8</sub> in toluene/diethyl ether in the presence of naphthalene or 1-methylnaphthalene generates the dinuclear naphthalene-bridged species  $[(\text{L})\text{Ln}]_2(\mu\text{-C}_{10}\text{H}_7\text{R})$  (R = H, Me; Ln = Y, Lu), in which each Ln atom has  $\eta^4$ -coordination to opposite sides of the dianionic naphthalene ligand. Similarly, reaction of anthracene with  $(\text{L})\text{LnCl}(\text{THF})$  (Ln = Y, Lu) in the presence of KC<sub>8</sub> yields  $[(\text{L})\text{Ln}]_2(\mu\text{-C}_{14}\text{H}_{10})$  (Ln = Y, Lu).<sup>103</sup> Related

**Figure 69**  $[(\text{syn-PhP}[\text{CH}_2(\text{SiMe}_2)\text{N}(\text{SiMe}_2)\text{CH}_2]_2\text{PPh})\text{Y}]_2(\mu\text{-}\eta^6\text{:}\eta^6\text{-Ph}_2)$  (Ph and Me groups are omitted)

lanthanide(III) complexes with a bridging naphthalene dianion  $[(\text{THF})_3\text{LnI}_2]_2(\mu\text{-C}_{10}\text{H}_8)$  ( $\text{Ln} = \text{La}, \text{Ce}, \text{Pr}, \text{Nd}$ ) were synthesized by reaction of  $\text{LnI}_3(\text{THF})_3$  with equimolar amounts of Li metal and excess of  $\text{C}_{10}\text{H}_8$  in THF.  $[(\text{DME})_2\text{LnI}]_2(\mu\text{-C}_{10}\text{H}_8)$  ( $\text{Ln} = \text{Eu}, \text{Yb}$ ) were prepared in the same manner using  $\text{LnI}_2$  in DME. The X-ray structure determination of the La and Eu complexes show two  $\text{LaI}_2(\text{THF})_3$  and  $\text{EuI}(\text{DME})_2$  moieties, respectively, bridged by  $\eta^4$  bonded nonplanar naphthalene molecules. In contrast, reaction of  $\text{TmI}_2$  with two equivalents of  $\text{Li}[\text{C}_{10}\text{H}_8]$  in DME yields a binuclear  $\text{Tm(III)}$  complex with one bridging and two terminal naphthalene dianions  $[\text{Tm}(\text{DME})]_2(\eta^2\text{-C}_{10}\text{H}_8)_2(\mu^2\text{-}\eta^4\text{:}\eta^4\text{-C}_{10}\text{H}_8)$  (Figure 70).

Mononuclear lanthanide(III) complexes with terminal naphthalene dianions  $\text{CpLn}(\eta^2\text{-C}_{10}\text{H}_8)(\text{DME})$  ( $\text{Ln} = \text{Y}, \text{Gd}, \text{Er}, \text{Tm}, \text{Lu}$ ) have been prepared by the reaction of  $\text{CpLnCl}_2(\text{THF})_3$  with  $\text{Na}[\text{C}_{10}\text{H}_8]$  in DME (Figure 71a). The molecular structure of the yttrium and lutetium compound revealed that one naphthalene ring is bent, while the second one, which is not coordinated by the metal is planar. Two structurally related complexes of La(III) and Sm(III) with a bridging anthracene dianion  $(\text{Cp}^*_2\text{Ln})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-C}_{14}\text{H}_{10})$  ( $\text{Ln} = \text{La}, \text{Sm}$ ) were prepared by reaction of  $(\text{Cp}^*_2\text{La})(\mu\text{-Cl})_2\text{K}(\text{DME})_2$  with disodium anthracenide and by direct reduction of anthracene with decamethylsamarocene in toluene, correspondingly. The molecules contain two  $\text{Cp}^*_2\text{Ln}$  moieties, which are  $\eta^3$ -coordinated to two aromatic rings from opposite sides of the anthracene ligand (Figure 71b), which, in contrast to the complexes mentioned above, maintains its planarity. Bent anthracene dianions have also been found in  $\text{CpLu}(\eta^2\text{-C}_{14}\text{H}_{10})(\text{THF})_2$ ,  $[\text{Na}^+(\text{diglyme})_2][\text{Cp}_2\text{Lu}(\eta^2\text{-C}_{14}\text{H}_{10})]$ , and  $(\text{DME})_2\text{TmI}(\eta^2\text{-C}_{14}\text{H}_{10})$ .

2,3-benzanthracene and pyrene readily react with  $\text{Cp}^*_2\text{Sm}$  to give  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-Arene})$  ( $\text{Arene} = \text{C}_{18}\text{H}_{12}$  and

$\text{C}_{16}\text{H}_{10}$ , respectively). In the benzanthracene derivative, two  $\text{Cp}^*_2\text{Sm}$  fragments are coordinated at opposite edges of the nearly planar arene ligand and are located on the opposite faces of its plane in the manner similar to that in  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-C}_{14}\text{H}_{10})$ . In contrast, the metallocene moieties in  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-pyrene})$  are coordinated at the neighboring edges of the pyrene ligand above and below its plane. Reaction of  $(\text{Cp}^*\text{LaCl})(\mu\text{-Cl})_2\text{Li}(\text{THF})_2$  with pyrene in toluene in the presence of potassium yields  $(\text{Cp}^*\text{LaCl})_3(\mu^3\text{-C}_{16}\text{H}_{10})(\text{THF})$ . All three  $\text{Cp}^*\text{LaCl}$  moieties are located above one plane of the pyrene ligand and bridged by Cl atoms. Two La atoms are  $\eta^6$ -bonded to the arene ligand, whereas the third one is coordinated by one THF and has only two short La–C(pyrene) contacts (Figure 72).

Complexes of the lanthanides with heterocyclic aromatic ligands have been also reported, for example,  $(\text{Cp}^*_2\text{La})_2(\mu\text{-Arene})$  ( $\text{Arene} = 2,3\text{-dimethylquinoxaline}$  or  $\text{phenazine}$ ). Phenazine is reduced by  $\text{Cp}^*_2\text{Sm}$  yielding  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-C}_{12}\text{H}_8\text{N}_2)$  (Figure 73a), in which the samarocene fragments are in transoid orientation with respect to the  $(\text{C}_{12}\text{H}_8\text{N}_2)^{2-}$  dianion. Three short contacts between the samarium atoms and the phenazine ligand suggest an allylic type of bonding. Reduction of acridine with  $\text{Cp}^*_2\text{Sm}$ , independent of the reagents ratio, results in dimerization of two arene ligands via C–C bond formation. An ytterbium complex containing the antiaromatic 2,2'-bipyridyl ligand has been prepared by reduction of 2,2'-bipyridine with  $\text{Yb}(\text{C}_{10}\text{H}_8)(\text{THF})_2$  as the cyclic trimer  $[\text{Yb}(\mu^2\text{-N}_2\text{C}_{10}\text{H}_8)(\text{THF})_2]_3$  in which the Yb atoms are bridged by 2,2'-bipy ligands (Figure 73b).

Figure 70  $[\text{Tm}(\text{DME})]_2(\eta^2\text{-C}_{10}\text{H}_8)_2(\mu^2\text{-}\eta^4\text{:}\eta^4\text{-C}_{10}\text{H}_8)$

Figure 71 (a)  $\text{CpLu}(\eta^2\text{-C}_{10}\text{H}_8)(\text{DME})$ , (b)  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-C}_{14}\text{H}_{10})$

**Figure 73** (a)  $(\text{Cp}^*_2\text{Sm})_2(\mu\text{-}\eta^3\text{:}\eta^3\text{-C}_{12}\text{H}_8\text{N}_2)$ , (b)  $[\text{Yb}(\mu^2\text{-N}_2\text{C}_{10}\text{H}_8)(\text{THF})_2]_3$

### 8.3 Boratabenzene Complexes

Lithium 1-aminoboratabenzenes react with lanthanide trihalides in toluene to give the stepped ladder dimers  $[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2\text{Y}(\mu\text{-Cl})_2\text{Li}]_2$  (Figure 74a),  $[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2\text{Lu}(\mu\text{-Cl})_2\text{Li}]_2$ , and the mononuclear complexes  $\text{YCl}[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}(\text{SiMe}_3)_2)_2]$ ,  $\text{LuCl}[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}(\text{SiMe}_3)_2)_2]$ , and  $\text{ScCl}[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}^i\text{Pr}_2)_2]$  (Figure 74b). The same reactions in THF or THP yield solvated complexes  $(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2\text{Sm}(\mu\text{-Cl})_2\text{Li}(\text{THF})$ ,  $(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2\text{Y}(\mu\text{-Cl})_2\text{Li}(\text{THP})$ ,  $(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}^i\text{Pr}_2)_2\text{Y}(\mu\text{-Cl})_2\text{Li}(\text{THF})_2$ ,  $(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}^i\text{Pr}_2)_2\text{Sm}(\mu\text{-Cl})_2\text{Li}(\text{THF})_2$ , and the *ansa* complexes  $[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMeCH}_2)_2]\text{Lu}(\mu\text{-Cl})_2\text{Li}(\text{THF})_2$  and  $[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMeCH}_2)_2]\text{Lu}(\mu\text{-Cl})_2\text{Li}(\text{THP})_2$ .<sup>104</sup>

Reaction of yttrium trichloride with lithium 1-methylboratabenzene in toluene affords donor-free dinuclear  $[(\text{C}_5\text{H}_5\text{BMe})_2\text{Y}(\mu\text{-Cl})_2]$ . Bis(boratabenzene)scandium complexes  $[\text{ScCl}(\text{C}_5\text{H}_5\text{BMe})_2]_2$ ,  $[\text{ScCl}(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2]_2$ , and  $\text{ScCl}[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}(\text{SiMe}_3)_2)_2]$  were synthesized from solvent-free Li boratabenzenes and  $\text{ScCl}_3$  in toluene.  $[\text{ScCl}(\text{C}_5\text{H}_5\text{BMe})_2]_2$  (Figure 75a) possesses a double chloro-bridged dinuclear structure with four facially coordinated boratabenzene ligands. In contrast, in  $[\text{ScCl}(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2]_2$ , each Sc atom binds to one boratabenzene in an unprecedented N–B–C-2 coordination mode and facially to the second boratabenzene ligand (Figure 75b).  $\text{ScCl}[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}(\text{SiMe}_3)_2)_2]$  is mononuclear because of the bulkiness of its boratabenzene ligands. The

**Figure 74** (a)  $[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2\text{Y}(\mu\text{-Cl})_2\text{Li}]_2$ , (b)  $\text{ScCl}[(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BN}^i\text{Pr}_2)_2]_2$

**Figure 75** (a)  $[\text{ScCl}(\text{C}_5\text{H}_5\text{BMe})_2]_2$ , (b)  $[\text{ScCl}(3,5\text{-Me}_2\text{C}_5\text{H}_3\text{BNMe}_2)_2]_2$

**Figure 76**  $(\text{THF})(\text{BH}_4)_2\text{Nd}(\mu\text{-}\eta^7\text{:}\eta^7\text{-C}_7\text{H}_7)\text{Nd}(\text{BH}_4)(\text{THF})_3$

reaction of  $\text{C}_5\text{H}_5\text{B-PMe}_3$  with  $\text{Ph}_3\text{Sc}(\text{THF})_2$  provides  $(\text{C}_5\text{H}_5\text{B-Ph})\text{ScPh}_2(\text{THF})$ .

## 9 CYCLOHEPTATRIENYL COMPLEXES

Only one cycloheptatrienyl complex of the lanthanides is known until now. Reaction of  $\text{Nd}(\text{BH}_4)_3(\text{THF})_2$  with  $\text{K}(\text{C}_7\text{H}_9)$  yields  $(\text{THF})(\text{BH}_4)_2\text{Nd}(\mu\text{-}\eta^7\text{:}\eta^7\text{-C}_7\text{H}_7)\text{Nd}(\text{BH}_4)(\text{THF})_3$  (Figure 76). The X-ray structure determination shows a unique reverse-sandwich structure with both Nd atoms  $\eta^7$  coordinated to the planar ligand.

## 10 CYCLOOCTATETRAENYL COMPLEXES

### 10.1 Mono(cyclooctatetraenyl) Complexes

Cyclooctatetraenyl lanthanide(III) halides of the type  $[(\text{COT})\text{Ln}(\mu\text{-Cl})(\text{THF})_2]_2$  (Figure 77a) are the most important precursors for the preparation of other half-sandwich (see *Half-sandwich Complexes*) and mixed sandwich complexes with cyclooctatetraenyl ligands. These complexes are readily accessible by reacting anhydrous lanthanide trichlorides with  $\text{K}_2[\text{COT}]$  in a molar ratio of 1:1. The compounds consist of centrosymmetric, chloro-bridged dimers with

$\eta^8$ -coordinated cyclooctatetraenyl ligands. The use of the sterically demanding 1,4-bis(trimethylsilyl)cyclooctatetraenyl ligand allows the synthesis of a related series of organolanthanide halides  $[\text{Ln}\{(1,4\text{-}(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6)\}(\mu\text{-Cl})(\text{THF})]_2$  ( $\text{Ln} = \text{Y}, \text{Sm}, \text{Ho}, \text{Lu}$ ). The anionic complex  $[\text{Li}(\text{diglyme})_2][\{(1,4\text{-}(\text{Me}_2\text{SiC}_6\text{H}_4\text{NMe}_2\text{-o})_2\text{C}_8\text{H}_6)_2\text{Sm}_2(\mu\text{-Cl})_3\}]$  (Figure 77b) has a triple chlorine bridge between two Sm atoms.

Mononuclear iodo complexes  $(\text{COT})\text{LnI}(\text{THF})_n$  ( $\text{Ln} = \text{La}, \text{Ce}, \text{Pr}, n = 3$ ;  $\text{Ln} = \text{Nd}, n = 2$ ;  $\text{Ln} = \text{Sm}, n = 1$ ) can be prepared either by reaction of  $\text{LnI}_3$  with  $\text{K}_2[\text{COT}]$  in THF ( $\text{Ln} = \text{Nd}, \text{Sm}$ ), or directly from metal powders, iodine, and COT ( $\text{Ln} = \text{La}, \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}$ ) in THF. The Tm complex  $(\text{COT})\text{TmI}(\text{THF})_2$  is formed by reduction of COT with  $\text{TmI}_2$  in THF. An improved solubility in polar organic solvents was also found for the corresponding mono(cyclooctatetraenyl)lanthanide triflates  $[(\text{COT})\text{Ln}(\mu\text{-O}_3\text{SCF}_3)(\text{THF})_2]_2$ . Mono(cyclooctatetraenyl)lanthanide complexes  $(\text{COT})\text{Ln}(\text{BH}_4)(\text{THF})_n$  can be prepared from  $\text{Ln}(\text{BH}_4)_3(\text{THF})_3$  and  $\text{K}_2[\text{COT}]$ .  $(\text{COT})\text{Nd}(\text{BH}_4)(\text{THF})_2$  loses one THF upon recrystallization forming the dimer  $[(\text{COT})\text{Nd}(\mu\text{-BH}_4)(\text{THF})]_2$ . Protonation of  $(\text{COT})\text{Nd}(\text{BH}_4)(\text{THF})_2$  with  $[\text{NH}_4\text{Et}_3][\text{BPh}_4]$  provides a convenient access to the cationic mono(cyclooctatetraenyl)neodymium(III) complex  $[(\text{COT})\text{Nd}(\text{THF})_4][\text{BPh}_4]$ . Its X-ray crystal structure reveals the presence of discrete cation–anion pairs in the solid state with the Nd ions being in a slightly distorted square-pyramidal coordination environment. Replacement of the THF ligands in  $[(\text{COT})\text{Nd}(\text{THF})_4][\text{BPh}_4]$  with HMPA yields  $[(\text{COT})\text{Nd}(\text{HMPA})_3][\text{BPh}_4]$ .

Mono(cyclooctatetraenyl)lanthanide(III) complexes containing additional group 16 donor ligands  $[(\text{COT})\text{Ln}(\mu\text{-OR})(\text{THF})_2]_2$  ( $\text{Ln} = \text{Y}, \text{Lu}, \text{R} = \text{Ph}, 2,6\text{-C}_6\text{H}_3\text{Me}_2$ ;  $\text{Ln} = \text{Dy}, \text{R} = (\text{CH}_2)_3\text{CH}=\text{CH}_2$ ;  $\text{Ln} = \text{Nd}, \text{R} = \text{Et}$ ) were prepared from  $[(\text{COT})\text{Ln}(\mu\text{-Cl})(\text{THF})_2]_2$  or  $(\text{COT})\text{Ln}(\text{BH}_4)(\text{THF})_n$  and NaOR. Three representatives,  $[(\text{COT})\text{Y}(\mu\text{-OPh})(\text{THF})]_2$  (Figure 78a),  $[(\text{COT})\text{Nd}(\mu\text{-OEt})(\text{THF})]_2$ , and  $[(\text{COT})\text{Dy}\{\mu\text{-O}(\text{CH}_2)_3\text{CH}=\text{CH}_2\}(\text{THF})]_2$  have been structurally characterized. Other sterically more demanding alkoxides and

**Figure 77** (a)  $[(\text{COT})\text{Ln}(\mu\text{-Cl})(\text{THF})_2]_2$ , (b)  $[\text{Li}(\text{diglyme})_2][1,4\text{-}(\text{Me}_2\text{SiC}_6\text{H}_4\text{NMe}_2\text{-o})_2(\text{C}_8\text{H}_6)_2\text{Sm}_2(\mu\text{-Cl})_3]$

**Figure 78** (a)  $[(\text{COT})\text{Y}(\mu\text{-O}^i\text{Pr})(\text{THF})]_2$ , (b)  $\{[\text{Zr}_2(\text{O}^i\text{Pr})_9]\text{Sm}\}_2(\text{COT})$

siloxides are  $(\text{COT})\text{Ln}(\text{OC}^i\text{Bu}_3)(\text{THF})$ ,  $(\text{COT})\text{Ln}(\text{OSiPh}_3)(\text{THF})$  ( $\text{Ln} = \text{Y}, \text{Lu}$ ),  $\text{Ln}[1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6](\text{OC}_6\text{H}_2\text{-}2,6\text{-}^i\text{Bu}_2\text{-}4\text{-Me})(\text{THF})$  ( $\text{Ln} = \text{Sc}, \text{Y}$ ),  $[\{1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6\}\text{Sm}(\mu\text{-OAr})]_2$  ( $\text{Ar} = \text{C}_6\text{H}_2(^i\text{Bu})_2\text{-}2,6\text{-Me-}4$ ), and  $\{[\text{Zr}_2(\text{O}^i\text{Pr})_9]\text{Ln}\}_2(\text{COT})$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) (Figure 78b).

The preparation of mono(cyclooctatetraenyl)samarium(III) thiolates and selenolates  $[(\text{COT})\text{Sm}(\mu\text{-EAr})(\text{THF})_n]_2$  ( $n = 1$ ,  $\text{EAr} = 2,4,6\text{-SC}_6\text{H}_2^i\text{Pr}_3$ ;  $n = 2$ ,  $\text{EAr} = \text{SPh}, \text{SePh}, 2,4,6\text{-SC}_6\text{H}_2^i\text{Pr}_3$ ) has been achieved by the reaction of samarium powder with COT in THF in the presence of diaryl disulfides or diselenides. The molecular structure of  $[(\text{COT})\text{Sm}(\mu\text{-SePh})(\text{THF})_2]_2$  reveals a dimeric molecule with phenylselenolate bridges. Monomeric organosamarium thiolates have been prepared in the same manner with use of either sterically demanding or potentially chelating thiolate ligands, for example,  $(\text{COT})\text{Sm}(\text{SC}_5\text{H}_4\text{N})[\text{OP}(\text{NMe}_2)_3]_2$  (Figure 79a) or  $[\text{Na}(\text{THF})_2][(\text{COT})\text{Nd}(\text{S}^i\text{Bu})_2]$ . A number of lanthanide mono(cyclooctatetraenyl)/amide complexes

$(\text{COT})\text{Ln}[\text{N}(\text{SiMe}_3)_2](\text{THF})$  ( $\text{Ln} = \text{Y}, \text{Gd}, \text{Er}, \text{Lu}$ ) has been synthesized by the reactions of  $[(\text{COT})\text{Ln}(\mu\text{-Cl})(\text{THF})_2]_2$  with two equiv. of  $\text{NaN}(\text{SiMe}_3)_2$ . An unusual ‘inverse sandwich complex’ is obtained when the same reaction is carried out with  $[(\text{COT})\text{Sm}(\mu\text{-Cl})(\text{THF})_2]_2$ .  $[\text{Sm}\{\text{N}(\text{SiMe}_3)_2\}_2](\mu\text{-COT})$  shows two  $\text{Sm}\{\text{N}(\text{SiMe}_3)_2\}_2$  units symmetrically bridged by the cyclooctatetraenyl ligand (Figure 79b). A closely related ‘inverse sandwich complex’ of divalent samarium  $(\mu\text{-COT})[\text{Sm}\{\text{N}(\text{SiMe}_3)_2\}(\text{THF})_2]_2$  has a planar  $(\text{COT})^{2-}$  ring, sandwiched between two  $[(\text{Me}_3\text{Si})_2\text{N}\text{Sm}(\text{THF})_2]^+$  cations. This structure is similar to that of the pentamethylcyclopentadienyl derivative  $[\text{Cp}^*\text{Ln}(\text{THF})_2]_2(\mu\text{-COT})$  ( $\text{Ln} = \text{Sm}, \text{Eu}, \text{Yb}$ ), prepared by the reaction of  $[\text{Cp}^*\text{Ln}(\mu\text{-I})(\text{THF})_2]_2$  ( $\text{Ln} = \text{Sm}, \text{Eu}, \text{Yb}$ ) with one equiv. of  $\text{K}_2[\text{C}_8\text{H}_8]$  in toluene. Dissolution of those complexes at 30 to 50° C under vacuum yields  $[\text{Cp}^*\text{Ln}]_2(\mu\text{-}\eta^8\text{:}\eta^8\text{-COT})$  (Figure 79c).

The reaction of  $(\text{COT})\text{LnCl}(\text{THF})_n$  compounds with the lithium, sodium, or potassium salts of  $\text{C}_5\text{H}_6$ ,

**Figure 79** (a)  $(\text{COT})\text{Sm}(\text{SC}_5\text{H}_4\text{N})[\text{OP}(\text{NMe}_2)_3]_2$ , (b)  $[\text{Sm}\{\text{N}(\text{SiMe}_3)_2\}_2]_2(\mu\text{-COT})$ , (c)  $[\text{Cp}^*\text{Sm}]_2(\mu\text{-COT})$

$C_5H_2Me_4$ ,  $C_5HMe_5$ ,  $C_5HMe_4Et$ ,  $C_5H_3(SiMe_3)_2$ ,  $C_5HPh_5$ ,  $C_5H_5CH_2Ph$ ,  $C_5H_5C_5H_9$ , or indene produces a number of mixed cyclopentadienyl(cyclooctatetraenyl)lanthanide complexes, such as  $(COT)Ln(C_5Me_4R)(THF)_n$ ,  $(COT)Ln(Cp^*)$ ,  $(COT)Pr(C_5Ph_5)$ ,  $(COT)Gd(C_6H_5CH_2C_5H_4)(DME)$ ,  $[(COT)Nd(\mu-\eta^8-COT)K(THF)(\eta^3-C_6H_5CH_2-\mu^2-\eta^5-C_5H_4)-Nd(THF)_2(\eta^8-COT)]$ ,  $(COT)Ln(C_5H_9C_5H_4)(THF)_2$ ,  $(COT)Gd(C_5H_9C_5H_4)(THF)$ , and  $(Ind)Ln(COT)(THF)_2$ .

Mixed chiral cyclooctatetraenyl cyclopentadienyl lanthanide complexes  $(COT)Sm\{(S)-\eta^5:\eta^1-C_5H_4CH_2CHMeOMe\}$ ,  $(COT)Ln\{(S)-\eta^5:\eta^1-C_5H_4CH_2CHMeNMe_2\}$ ,  $(COT)Ln\{(S)-\eta^5:\eta^1-C_5H_4CHPhCH_2NMe_2\}$  (Figure 80a), and achiral  $(COT)Ln(\eta^5:\eta^1-C_5H_4CH_2CH_2NMe_2)$  ( $Ln = Sm, Lu$ ), which bear O- and N-donor-functionalized Cp-ligands,

**Figure 80** (a)  $(COT)Y\{(S)-\eta^5:\eta^1-C_5H_4CHPhCH_2NMe_2\}$ , (b)  $(\eta^5:\eta^1-MeOCH_2CH_2C_9H_6)Sm(COT)(THF)$

have been synthesized by reactions of  $[(COT)Ln(\mu-Cl)(THF)]_2$  ( $Ln = Sm, Lu$ ) with respective cyclopentadienyl potassium salts.<sup>105</sup> Mixed COT/indenyl complexes with donor-functionalized indenyl ligands  $(\eta^5:\eta^1-MeOCH_2CH_2C_9H_6)Ln(COT)(THF)_n$  (Figure 80b) ( $Ln = La, Nd, n = 0$ ;  $Sm, Dy, Er, n = 1$ ) and  $(\eta^5:\eta^1-C_4H_7OCH_2C_9H_6)Ln(COT)(THF)$  ( $Ln = La, Nd, Sm, Dy, Er$ ) were synthesized by the reactions of  $LnCl_3$  with equimolar amounts of  $K_2[COT]$ , followed by treatment with the corresponding potassium salt of ether-substituted indenide.<sup>106</sup>

Reactions of  $K[C_5Me_4PMe_2]$ ,  $Li[C_5H_4PPh_2]$ , and  $K[C_5Me_4PPh_2]$  with  $[(COT)Sm(\mu-Cl)(THF)]_2$  yield a series of COT complexes  $(COT)Sm(C_5R_4PR'_2)(THF)_n$  (Figure 81a) ( $R = H$  or  $Me$ ;  $R' = Me$  or  $Ph$ ;  $n = 0$  or  $2$ ). They react with  $CpRh(CO)_2$  affording phosphido-bridged bimetallic samarium(III)-rhodium(I) complexes  $(COT)Sm(\mu-C_5R_4PR'_2)Rh(Cp)(CO)$  ( $R = H$  or  $Me$ ;  $R' = Me$  or  $Ph$ ). 3,4-Dimethyl-2,5-bis(trimethylsilyl)phospholyl (Dsp) derivatives  $(COT)Sm(Dsp)$  and  $(COT)Nd(Dsp)(THF)$  (Figure 81b) have also been prepared.<sup>107</sup> COT/pyrrolyl complexes  $(COT)Ln(\eta^5-pyr^*)(THF)_n$  (Figure 81c) ( $Ln = Sm, n = 1$ ;  $Ln = Tm, Lu, n = 0$ ) were prepared from  $[(COT)Ln(\mu-Cl)(THF)]_2$  and  $Na(pyr^*)$  ( $pyr^* = NC_4H_2'Bu_{2-2,5}$ ).

Polydentate nitrogen ligands are very suited to stabilize mono(cyclooctatetraene) lanthanide(III) complexes. These include silylated benzamidinates  $[RC_6H_4C(NSiMe_3)_2]Ln-(COT)(THF)$  ( $Ln = Y, Ce, Pr, Nd, Sm, Tm, Lu$ ;  $R = H, MeO, CF_3$ ) (Figure 82a) and diiminophosphinates

**Figure 81** (a)  $(COT)Sm(C_5H_4PPh_2)(THF)_2$ , (b)  $(COT)Nd(Dsp)(THF)$ , (c)  $(COT)Sm(pyr^*)(THF)$

**Figure 82** (a)  $[RC_6H_4C(NSiMe_3)_2]Sm(COT)(THF)$ , (b)  $[Ph_2P(NSiMe_3)_2]Sm(COT)(THF)$ , (c)  $[HB(C_3N_2Me_2)_3]Lu(COT)$

$[\text{Ph}_2\text{P}(\text{NSiMe}_3)_2]\text{Ln}(\text{COT})(\text{THF})$  ( $\text{Ln} = \text{Y}, \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}$ ) (Figure 82b), as well as tridentate pyrazolylborates  $[\text{HB}(\text{C}_3\text{N}_2\text{R}_2)_3]\text{Ln}(\text{COT})$  ( $\text{Ln} = \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}, \text{Lu}$ ;  $\text{R} = \text{H}, \text{Me}$ ) (Figure 82c).

Complexes of the type  $[1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6]\text{Ln}(\text{DAD})$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ;  $\text{DAD} = 1,4\text{-diazadiene}$ ) have been prepared in a 'one-pot' reaction by treatment of elemental samarium or ytterbium with equimolar amounts of 1,4-bis(trimethylsilyl)cyclooctatriene and substituted 1,4-diazadiene ligands.  $^1\text{H}$  and  $^{171}\text{Yb}$  NMR data revealed that the Sm derivatives contain  $\text{Sm}^{3+}$  ions and coordinated DAD radical anions, while, in the case of Yb, the neutral DAD ligand is coordinated to divalent ytterbium. The  $^{171}\text{Yb}$  NMR spectrum of  $[1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6]\text{Yb}[\text{PhN}=\text{C}(\text{Me})\text{C}(\text{Me})=\text{NPh}]$  shows a single resonance at  $\delta 224.3$  ppm, which is consistent with the presence of an  $\text{Yb}^{2+}$  complex. Recently a series of half-sandwich complexes containing the same ligand in combination with aminotroponiminates have been prepared and characterized (Figure 83).<sup>108</sup>

## 10.2 Bis(cyclooctatetraenyl) Complexes

Shortly after the synthesis of uranocene (*see Uranocene*), the first lanthanide complexes containing the cyclooctatetraenyl dianion,  $\text{K}[\text{Ln}(\text{COT})_2]$ , have been prepared by the reaction of  $\text{K}_2[\text{COT}]$  with lanthanide trichlorides (equation 21).

They are thermally very robust, but decompose almost explosively upon contact with traces of oxygen. X-ray

**Figure 83**  $[1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6]\text{Ln}[\text{C}_7\text{H}_5(\text{N}^i\text{Pr})_2](\text{THF})$

**Figure 84** (a)  $[\text{Na}(\text{THF})_3][\text{Sm}(\text{COT})_2]$ , (b)  $[(\text{COT})\text{Er}(\mu\text{-COT})\text{K}(\mu\text{-COT})\text{Er}(\mu\text{-COT})\text{K}(\text{THF})_4]$

diffraction studies showed  $[\text{Li}(\text{THF})_4][\text{Ln}(\text{COT})_2]$  ( $\text{Ln} = \text{Ce}, \text{Sm}$ ) consisting of separated ions with the lithium cation being coordinated by four THF molecules.  $[\text{Na}(\text{THF})_3][\text{Sm}(\text{COT})_2]$  (Figure 84a) forms a double sandwich with two COT ligands and the two metal ions arranged as a linear unit. A very similar molecular structure was reported for the solvated potassium salt  $[\text{K}(\text{diglyme})][\text{Ce}(\text{COT})_2]$ . The X-ray structure of  $[(\text{COT})\text{Er}(\mu\text{-COT})\text{K}(\mu\text{-COT})\text{Er}(\mu\text{-COT})\text{K}(\text{THF})_4]$  (Figure 84b) shows that the stacking of cyclooctatetraene ligands in organolanthanide complexes can be further extended.

Several examples of anionic sandwich complexes containing substituted cyclooctatetraenyl ligands have been reported also, for example,  $[\text{Li}(\text{THF})_4][\text{Ln}\{1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6\}_2]$  ( $\text{Ln} = \text{Y}, \text{Ce}, \text{Pr}, \text{Nd}, \text{Sm}$ ). The very bulky 1,3,6-tris(trimethylsilyl)cyclooctatetraenyl ligand as well as functionally substituted cyclooctatetraenyl ligands  $1,4\text{-R}_2\text{C}_8\text{H}_6$  ( $\text{R} = o\text{-Me}_2\text{NC}_6\text{H}_4\text{SiMe}_2$ ) were also reported to form anionic sandwich complexes with nearly all rare earth elements. Alkali metal-free sandwich complexes  $[\text{Ln}(\text{COT})(\text{HMPA})_n]^+[\text{Ln}(\text{COT})_2]^-$  ( $\text{Ln} = \text{La}, n = 4$ ;  $\text{Ln} = \text{Sm}, n = 3$ ) were obtained by reaction of lanthanide metals with COT in the presence of a catalytic amount of iodine in THF containing HMPA. When a stoichiometric amount of iodine is used in this reaction,  $[\text{Sm}(\text{COT})(\text{HMPA})_3]^+(\text{I})^-$  is isolated. Bimetallic complexes containing  $[\text{Ln}(\text{COT})_2]^-$  anions, for example,  $[\text{CoCp}_2][\text{Ce}\{1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6\}_2]$  (Figure 85a) and  $[\text{Yb}(\text{THF})_6][\text{Ce}\{1,3,6-(\text{Me}_3\text{Si})_3\text{C}_8\text{H}_5\}_2]_2$  (Figure 85b) are also known.

## 11 ORGANOLANTHANIDES IN THE OXIDATION STATE 0, +1, +2 AND +4

### 11.1 Organolanthanides in the Oxidation State 0

There are just few examples of authentic lanthanide complexes in the oxidation state zero. Bis(arene) complexes of the lanthanides  $(1,3,5\text{-}t\text{Bu}_3\text{C}_6\text{H}_3)_2\text{Ln}$  ( $\text{Ln} = \text{Sc}, \text{Y}, \text{La}, \text{Nd}, \text{Pr}, \text{Sm}, \text{Gd}, \text{Tb}, \text{Dy}, \text{Ho}, \text{Er}, \text{Lu}$ ) have been synthesized by cocondensation of metal vapors (*see Metal Vapor Synthesis of Transition Metal Compounds*) with 1,3,5-tri(*tert*-butyl)benzene at 75 K. A sandwich structure with coplanar arene ligands has been proven by X-ray crystal structure analysis of the Gd and Ho complexes (Figure 86a).

**Figure 85** (a)  $[\text{CoCp}_2][\text{Ce}\{1,4-(\text{Me}_3\text{Si})_2\text{C}_8\text{H}_6\}_2]^+$ , (b)  $[\text{Yb}(\text{THF})_6][\text{Ce}\{1,3,6-(\text{Me}_3\text{Si})_3\text{C}_8\text{H}_5\}_2]^{2+}$

**Figure 86** (a)  $(t\text{Bu}_3\text{C}_6\text{H}_3)_2\text{Ho}$ , (b)  $(t\text{Bu}_3\text{C}_6\text{H}_3)\text{Sc}(\text{H})[(t\text{Bu})_2(\text{CMe}_2\text{CH}_2)\text{C}_6\text{H}_3]$ , (c)  $\text{Ho}(\text{PC}_5\text{H}_2\text{Bu}_3)_2$

An attempt to prepare the analogues complexes of Ce, Eu, Tm, and Yb failed, what has been explained on the basis of the difference in the promotion energy of  $f^n s^2 \rightarrow f^{n-1} d^1 s^2$  for different lanthanides. As in chloroaluminate lanthanide(III) complexes with neutral arene ligands, the stability of zerovalent bis(arene)lanthanides increases with increasing number and size of substituents at the aromatic ring. Cocondensation of Sc with tri-*tert*-butylbenzene results in the formation of the bis(arene)scandium complex together with  $(\eta^6\text{-}t\text{Bu}_3\text{C}_6\text{H}_3)\text{Sc}(\text{H})[(\eta^6\text{-}\eta^1\text{-}t\text{Bu})_2(\text{CMe}_2\text{CH}_2)\text{C}_6\text{H}_3]$  (Figure 86b) via insertion of Sc into the C–H bond of one *tert*-butyl substituent. Cocondensation of Ho vapor with 2,4,6-tri-*tert*-butylphosphorin yields  $\text{Ho}(\eta^6\text{-PC}_5\text{H}_2\text{Bu}_3\text{-}2,4,6)_2$  (Figure 86c), which sublimates with 90% recovery at  $160^\circ\text{C}/10^{-5}$  mbar.

**Figure 87** (a)  $[(\text{Et}_2\text{NCH}_2\text{CH}_2\text{NCMeCHCMeNCH}_2\text{CH}_2\text{NEt}_2)\text{MgBr}]_2\text{ScBr}$ , (b)  $(t\text{Bu}_2\text{C}_2\text{P}_3)\text{Sc}(\mu\text{-}t\text{Bu}_3\text{C}_3\text{P}_3)\text{Sc}(t\text{Bu}_2\text{C}_2\text{P}_3)$

## 11.2 Organolanthanides in the Oxidation State 1

Organometallic compounds of the 4f-elements in the oxidation state +1 are not reported until now. There are only two examples of monovalent scandium complexes. Thus, the  $\beta$ -diketiminato derivative of scandium,  $\text{LScBr}_2$  ( $\text{L} = \text{Et}_2\text{NCH}_2\text{CH}_2\text{NC}(\text{Me})\text{CHC}(\text{Me})\text{NCH}_2\text{CH}_2\text{NEt}_2$ ) reacts with  $(\text{C}_3\text{H}_5)\text{MgBr}$  yielding  $(\text{LMgBr})_2\text{ScBr}$  (Figure 87a). X-ray structure, liquid and solid-state NMR, EPR-, UV-vis-spectroscopy, and magnetic measurements support a formal oxidation state of Sc(I) having no unpaired

electrons.<sup>109</sup> Cocondensation of Sc with 2,2-dimethylpropylidynephosphine,  $\text{Me}_3\text{CC}\equiv\text{P}$ , affords the triple-decker sandwich complex  $(\eta^5\text{-}t\text{Bu}_2\text{C}_2\text{P}_3)\text{Sc}(\mu\text{-}\eta^6\text{-}\eta^6\text{-}t\text{Bu}_3\text{C}_3\text{P}_3)\text{Sc}(\eta^5\text{-}t\text{Bu}_2\text{C}_2\text{P}_3)$ , which was characterized by X-ray crystallography (Figure 87b).

## 11.3 Organolanthanides in the Oxidation State 2

Organometallic compounds of the lanthanides in the oxidation state Ln(II) were first reported in the early 1980s

and was limited to only Sm, Eu, and Yb. In 1997, the first divalent thulium complex (see *Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry*) was reported by Bochkarev *et al.* Since then, divalent Nd and Dy derivatives have been prepared and structurally characterized. The chemistry of those compounds is increasing because of their unique reactivity, which is associated with the reducing properties of the divalent lanthanide ions.

### 11.3.1 Divalent Alkyl Lanthanide Complexes

The reaction between  $\text{LnI}_2$  ( $\text{Ln} = \text{Eu}, \text{Yb}$ ) and  $\text{K}[\text{C}(\text{SiMe}_3)_3]$  in benzene yields solvent-free monomeric  $\text{Ln}[\text{C}(\text{SiMe}_3)_3]_2$ . The Yb derivative reacts with  $\text{Et}_2\text{O}$  or iodomethane yielding  $[\text{Yb}\{\text{C}(\text{SiMe}_3)_3\}(\mu\text{-OEt})(\text{OEt}_2)]_2$  and  $[\text{Yb}\{\text{C}(\text{SiMe}_3)_3\}\text{I}]_2$ , respectively, which are dimeric in the solid state. The Yb analogs of Grignard reagents,  $\text{Yb}[\text{C}(\text{SiMe}_3)_2(\text{SiMe}_2\text{X})]\text{I}(\text{OEt}_2)$  ( $\text{X} = \text{Me}, \text{CH}=\text{CH}_2, \text{Ph}, \text{or OMe}$ ) were prepared from Yb metal and RI [ $\text{R} = [\text{C}(\text{SiMe}_3)_2(\text{SiMe}_2\text{X})]$ ,  $\text{X} = \text{Me}, \text{CH}=\text{CH}_2, \text{or CH}_2\text{CH}_2\text{-OEt}$ ]. The alkylytterbium iodides crystallize from  $\text{Et}_2\text{O}$  as solvated iodide-bridged dimers in which the coordination at Yb is four when  $\text{X} = \text{Me}$  but is increased to five by

chelation from the group X when  $\text{X} = \text{OMe}$  (Figure 88a). A redistribution yielding  $\text{R}_2\text{Yb}$  and  $\text{YbI}_2$  is not observed when  $\text{X} = \text{Me}$ , but it takes place readily when  $\text{X} = \text{Ph}, \text{CH}=\text{CH}_2, \text{or OMe}$ . Reaction of  $\text{SmI}_2(\text{THF})_2$  with two equiv. of  $\text{K}[\text{C}(\text{SiMe}_3)_2(\text{SiMe}_2\text{OMe})]$  in THF results in the formation of  $\text{Sm}[\text{C}(\text{SiMe}_3)_2(\text{SiMe}_2\text{OMe})]_2(\text{THF})$  (Figure 88b).

The ether-solvated bis(trimethylsilyl)methyl derivative  $\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_2(\text{OEt}_2)_2$  is prepared from  $\text{YbI}_2$  and  $\text{Na}[\text{CH}(\text{SiMe}_3)_2]$ , the three-coordinate ytterbium(II) alkyl complex  $[\text{K}(\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3)]_n$  from  $\text{YbI}_2$  and three equiv. of  $\text{K}[\text{CH}(\text{SiMe}_3)_2]$  in benzene, and the red ate complex  $[\text{Li}(\text{THF})_4][\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3]$  by the reaction of LiR,  $\text{YbI}_2$ , and two equiv. of  $\text{K}[\text{CH}(\text{SiMe}_3)_2]$  in  $\text{Et}_2\text{O}$  in the presence of a small amount of THF.  $[\text{K}(\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3)]_\infty$  consists in the solid state of double chains of  $[\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3]^-$  anions linked by  $\text{K}^+$  cations (Figure 89a), whereas  $[\text{Li}(\text{THF})_4][\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3]$  has an ionic structure with isolated  $[\text{Li}(\text{THF})_4]^+$  cations and  $[\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3]^-$  anions (Figure 89b).<sup>110</sup> The mixed alkyl/alkoxy complexes  $[\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}(\text{OEt})(\text{L})_n]$  ( $\text{L} = \text{Et}_2\text{O}, n = 2; \text{L} = \text{THF}, n = 3$ ) were prepared from  $[\text{Yb}(\text{OEt})_2(\text{L})_n]$  and  $\text{K}[\text{CH}(\text{SiMe}_3)_2]$ .

Only two crystallographically characterized aryl derivatives of divalent lanthanides are reported. Reaction of Eu

**Figure 88** (a)  $[\text{YbC}(\text{SiMe}_3)_2(\text{SiMe}_2\text{OMe})(\text{THF})]_2(\mu\text{-I})_2$ , (b)  $\text{Sm}[\text{C}(\text{SiMe}_3)_2(\text{SiMe}_2\text{OMe})]_2(\text{THF})$

**Figure 89** (a)  $[\text{K}(\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3)]_\infty$ , (b)  $[\text{Li}(\text{THF})_4][\text{Yb}\{\text{CH}(\text{SiMe}_3)_2\}_3]$

metal with  $\text{Hg}(\text{C}_6\text{F}_5)_2$  in THF, followed by crystallization from THF/light petroleum affords  $\text{Eu}(\text{C}_6\text{F}_5)_2(\text{THF})_5$ , which reveals axial  $\text{C}_6\text{F}_5$  and equatorial THF ligands bonded to a pentagonal-bipyramidal Eu center (Figure 90a).<sup>111</sup> *m*-Terphenyl derivatives  $\text{Yb}(\text{Dpp})\text{I}(\text{THF})_3$  and  $\text{Eu}(\text{Dpp})_2(\text{THF})_2$  ( $\text{Dpp} = 2, 6\text{-Ph}_2\text{C}_6\text{H}_3$ ) were obtained from reactions of  $\text{DppI}$  with lanthanides in THF.<sup>112</sup> In  $\text{Yb}(\text{Dpp})\text{I}(\text{THF})_3$  (Figure 90b), the metal is bonded to the *ipso*-carbon atom of the terphenyl group, to the terminal iodo substituent, and to three THF molecules.  $\text{Eu}(\text{Dpp})_2(\text{THF})_2$  shows an Eu center in a distorted tetrahedral coordination environment.

$(\text{Ph}_3\text{Ge})_2\text{Eu}(\text{DME})_3$  (Figure 91a) was synthesized by reacting  $\text{Ph}_3\text{GeH}$  with  $\text{C}_{10}\text{H}_8$   $\text{Eu}(\text{THF})_2$  in DME. The Eu atom is located in the center of the hexagonal bipyramid with axially positioned germeryl ligands. Six oxygen atoms of the DME ligands form an equatorial plane. The interrelated stannyl derivative  $(\text{Ph}_3\text{Sn})_2\text{Yb}(\text{THF})_4$  was

**Figure 90** (a)  $\text{Eu}(\text{C}_6\text{F}_5)_2(\text{THF})_5$ , (b)  $\text{Yb}(\text{Dpp})\text{I}(\text{THF})_3$

prepared by reaction of Yb with either  $\text{Ph}_3\text{SnCl}$ ,  $\text{PhSnCl}_3$ , or  $\text{Ph}_3\text{SnSnPh}_3$ . According to X-ray data, Sn is covalently bonded to Yb.  $\text{Ph}_2\text{SnCl}_2$  reacts with Yb with formation of  $[\text{Yb}_2\text{Cl}_2(\text{DME})_6]^{2+}$  and  $[(\text{Ph}_3\text{Sn})_3\text{Sn}]^-$  ions (Figure 91b). In the solid state, it consists of  $[(\text{Ph}_3\text{Sn})_3\text{Sn}]^-$  anions separated by  $[\text{Yb}_2\text{Cl}_2(\text{DME})_6]^{2+}$  cations with  $\mu_2$ -bridging chlorine atoms. A Sn–Sn bond formation also takes place when Sm or Yb reacts with  $\text{Me}_3\text{SnCl}$  in THF yielding  $[(\text{Me}_3\text{Sn})_3\text{Sn}]^-$  anions. However, in these cases, complexes with direct Ln–Sn bonds  $[(\text{Me}_3\text{Sn})_3\text{Sn}]_2\text{Ln}(\text{THF})_4$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) were isolated. According to X-ray crystallography, both molecules have a distorted octahedral structure in which the central Ln ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) atom is bonded to four oxygen atoms of THF in equatorial positions and two tin atoms of the  $(\text{Me}_3\text{Sn})_3\text{Sn}$  groups in axial positions.

$(\text{Ph}_3\text{Si})_2\text{Yb}(\text{THF})_4$  and  $(\text{Ph}_3\text{Ge})_2\text{Yb}(\text{THF})_4$  (Figure 92a) were synthesized by reaction of  $\text{Ph}_3\text{SiCl}$  or  $\text{Ph}_3\text{GeCl}$ , respectively, with ytterbium in THF. Both compounds have octahedral structures with axial silyl and germeryl groups. The reaction between  $\text{YbI}_2$  and  $\text{K}[\text{Sn}(\text{CH}_2^t\text{Bu})_3]$  affords diamagnetic  $[(^t\text{BuCH}_2)_3\text{Sn}]_2\text{Yb}(\text{THF})_2$  (Figure 92b). Reaction with one equiv. of  $\text{ArOH}$  or  $\text{Cp}^*\text{H}$  results in the formation of mixed-ligand complexes  $(\text{ArO})\text{YbSn}(\text{CH}_2^t\text{Bu})_3(\text{THF})_2$  and  $\text{Cp}^*\text{YbSn}(\text{CH}_2^t\text{Bu})_3(\text{THF})_2$ .  $\text{Cp}^*\text{YbSi}(\text{SiMe}_3)_3(\text{THF})_2$  was prepared by the reaction of  $\text{Cp}^*_2\text{Yb}(\text{OEt}_2)$  with one equiv. of  $\text{Li}[\text{Si}(\text{SiMe}_3)_3](\text{THF})_3$  in toluene.

The reaction of  $[(\text{DME})_2\text{YbI}]_2(\mu\text{-C}_{10}\text{H}_8)$  with  $\text{PhC}\equiv\text{CH}$  leads to the mixed iodo/ethynyl complex  $[\text{Yb}(\mu\text{-C}\equiv\text{CPh})(\text{DME})_2]_2$  (Figure 93a). According to X-ray diffraction analysis, the molecule consists of two  $\text{YbI}(\text{DME})_2$  units bridged by two  $\text{C}\equiv\text{CPh}$  groups. The central cyclic fragment  $\text{Yb}-\text{C}-\text{Yb}-\text{C}$  is planar. The homoleptic  $\text{Yb}(\text{II})$

**Figure 91** (a)  $(\text{Ph}_3\text{Ge})_2\text{Eu}(\text{DME})_3$ , (b)  $[\text{Yb}_2\text{Cl}_2(\text{DME})_6][(\text{Ph}_3\text{Sn})_3\text{Sn}]_2$

**Figure 92** (a)  $(\text{Ph}_3\text{Ge})_2\text{Yb}(\text{THF})_4$ , (b)  $[(^t\text{BuCH}_2)_3\text{Sn}]_2\text{Yb}(\text{THF})_2$

**Figure 93** (a)  $[\text{Yb}(\mu\text{-C}\equiv\text{CPh})(\text{I})(\text{DME})_2]_2$ , (b)  $\{\text{Yb}[\text{AlEt}_4]_2\}_n$

tetraalkylaluminate complexes  $\{\text{Yb}[\text{AlR}_4]_2\}_n$  were obtained by silylamide elimination from  $\text{Yb}[\text{N}(\text{SiMe}_3)_2]_2(\text{THF})_2$  and excess  $\text{AlR}_3$  ( $\text{R} = \text{Me}, \text{Et}, ^i\text{Bu}$ ). In the solid state,  $\{\text{Yb}[\text{AlEt}_4]_2\}_n$  (Figure 93b) is polymeric, constituted of  $[\text{Yb}(\text{AlEt}_4)]^+$  and  $[\text{Yb}(\text{AlEt}_4)_3]^-$  units, forming an intricate three-dimensional network. Both fragments are linked by bridging  $\alpha\text{-C}$  atoms and secondary  $\text{Yb}\cdots\text{H-C}$  agostic interactions combining  $\mu, \eta^1\text{-}, \mu, \eta^2\text{-}$ , and  $\mu, \eta^3\text{-}$  coordination modes that result in remarkably short  $\text{Yb}\cdots\text{Al}$  (2.809 Å) and a large range of  $\text{Yb}\cdots\text{C}$  (2.649–3.364 Å) distances.<sup>113</sup> The alkylaluminum adducts  $\text{Yb}[\text{N}(\text{SiMe}_3)_2]_2(\text{AlR}_3)_2$  were prepared from  $\text{Yb}[\text{N}(\text{SiMe}_3)_2]_2$  and  $\text{AlR}_3$  ( $\text{R} = \text{Me}, \text{Et}$ ).

### 11.3.2 Divalent Lanthanidocenes and Related Compounds

A variety of cyclopentadienyl, indenyl, fluorenyl, and other related ligands have been used for the synthesis of divalent lanthanidocenes. Most of the synthetic approaches employ metathetical reactions between lanthanide salts and alkali or alkaline-earth metal salts of the ligands. Till recently, only  $\text{Ln}(\text{II})$  complexes have been known for Sm, Eu, and Yb.<sup>114</sup> However, the synthetic routes using lanthanide metals are also known. Europium and ytterbium metal dissolved in liquid ammonia react with  $\text{Cp}^*\text{H}$  affording  $\text{Cp}^*_2\text{Ln}(\text{NH}_3)(\text{THF})$  ( $\text{Ln} = \text{Eu}, \text{Yb}$ ). Transmetalation of  $\text{Ti}(\text{C}_5\text{D}_5)$  or  $(\text{C}_5\text{H}_4\text{PPh}_2)\text{Ti}$  with Yb metal in DME yields  $(\text{C}_5\text{D}_5)_2\text{Yb}(\text{DME})$  and  $[(\text{C}_5\text{H}_4\text{PPh}_2)_2\text{Yb}(\text{DME})]$ , respectively. Diethylene glycol dimethyl ether (DIME) adducts  $[(\text{C}_5\text{H}_4\text{PPh}_2)_2\text{Eu}(\text{DIME})]$  and  $[(\text{C}_5\text{H}_4\text{PPh}_2)_2\text{Yb}(\text{DIME})]$  have been prepared analogously in THF, followed by crystallization from DME/DIME.

$\text{SmI}_2$  reacts with one or two equiv. of  $\text{Cp}^*\text{K}$  in THF yielding  $[\text{Cp}^*\text{Sm}(\mu\text{-I})(\text{THF})_2]_2$  and  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$ , respectively.  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  shows a bent metallocene (*see Bent Metallocenes*) structure in which the two  $\text{Cp}^*$  ring centroids and the two oxygen atoms of the THF ligands (Figure 94a) are arranged roughly tetrahedral around Sm.  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  can be dissolved at 75°C under high vacuum or under reflux in toluene to form  $\text{Cp}^*_2\text{Sm}$ , which was the

**Figure 94** (a)  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$ , (b)  $\text{Cp}^*_2\text{Sm}$

first reported solvent-free bis(cyclopentadienyl) compound of  $\text{Ln}(\text{II})$ . Even in the absence of coordinating solvent molecules it has a bent structure (Figure 94b).

Bis(dihydropyran) and mono(tetrahydropyran) solvates of  $\text{Cp}^*_2\text{Sm}$  have been prepared by displacing THF from  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  and  $\text{Cp}^*_2\text{Sm}(\text{DME})$  has been obtained as green crystals by the reaction of  $\text{SmCl}_2$  with  $\text{NaCp}^*$  in DME.

The reaction of  $\text{LnI}_2$  with  $\text{Na}(\text{C}_5\text{Me}_4\text{Pr})$  in THF yields  $(\text{C}_5\text{Me}_4\text{Pr})_2\text{Ln}(\text{THF})$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ); base-free ytterbocenes  $\text{Cp}^*_2\text{Yb}$ ,  $(\text{C}_5\text{HMe}_4)_2\text{Yb}$ , and  $(\text{C}_5\text{H}_3^i\text{Bu}_2)_2\text{Yb}$  have been prepared by refluxing their  $\text{Et}_2\text{O}$  adducts in toluene,<sup>115</sup> as well as bis(substituted cyclopentadienyl)lanthanide(II) complexes  $[(\text{Me}_3\text{Si})_2\text{CHC}_5\text{H}_4]_2\text{Ln}(\text{THF})_2$  ( $\text{Ln} = \text{Sm}, \text{Eu}, \text{Yb}$ ),  $(\text{Me}_2^i\text{BuSiC}_5\text{H}_4)_2\text{Yb}(\text{THF})_2$ ,  $(\{\text{Me}_2^i\text{BuSi}\}_2\text{C}_5\text{H}_3)_2\text{Ln}(\text{THF})_2$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ),  $[(\text{Me}_3\text{Si})_2\text{CHC}_5\text{H}_4]_2\text{Ln}$  ( $\text{Ln} = \text{Sm}, \text{Eu}, \text{Yb}$ ),  $(\text{Me}_2^i\text{BuSiC}_5\text{H}_4)_2\text{Yb}$ ,  $(\{\text{Me}_2^i\text{BuSi}\}_2\text{C}_5\text{H}_3)_2\text{Ln}$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ), and  $\text{Me}_2\text{Si}(\text{C}_5\text{H}_3\text{CH}\{\text{SiMe}_3\}_2)_2\text{Yb}(\text{THF})_2$  were synthesized from the appropriate  $\text{LnI}_2$  with the respective Na or K cyclopentadienide.<sup>116</sup> Other solvent stabilized lanthanidocenes are  $(\text{C}_5\text{H}_3^i\text{Bu}_2)_2\text{Yb}(\text{OEt}_2)$ ,  $(\text{C}_5\text{H}_3^i\text{Bu}_2)_2\text{Sm}(\text{DME})$ ,  $(\text{C}_5\text{H}_3^i\text{Bu}_2)_2\text{Yb}(\text{DME})$ , and  $(\text{C}_5\text{H}_2^i\text{Bu}_3)_2\text{Ln}(\text{L})$  ( $\text{Ln} = \text{Sm}, \text{L} = \text{THF}; \text{Ln} = \text{Sm}, \text{Yb}, \text{L} = 2, 6\text{-Me}_2\text{C}_6\text{H}_3\text{NC}$ ).<sup>117</sup> Octa-isopropyl lanthanidocenes, as well as hexa-*tert*-butyl lanthanidocenes of Sm, Eu, and Yb show no tendency towards coordination of donor solvent molecules or alkali salts. Deca-isopropyl lanthanidocenes have

**Figure 95** (a)  $(C_5^iPr_5)_2Eu$ , (b)  $Na^+[YbCp_3]^-$

been synthesized from Sm, Eu, and Yb and free penta-isopropylcyclopentadienyl radicals (equation 22). The hexa-, octa-, and deca-isopropyleuropocenes show fluorescence in daylight or under UV irradiation. Crystals of  $(C_5H^iPr_3)_2Eu$  and  $(C_5H^iPr_4)_2Eu$  show bent-sandwich complexes, whereas  $(C_5^iPr_5)_2Eu$  has an axial symmetry with parallel five-membered rings (Figure 95a).<sup>118</sup> Reduction of  $Cp_3Yb$  with  $Na^+[C_{10}H_8]^-$  in THF yields  $Na^+[YbCp_3]^-$  as a three-dimensional polymer in which  $\mu-\eta^5:\eta^5-Cp$  groups link sodium and ytterbium (Figure 95b).

Coordinated THF in bis(cyclopentadienyl)lanthanides(II) can be replaced by so-called *Wanzlick-Arduengo carbenes*.  $Cp^*_2Sm(THF)_2$  reacts with 1,3-diisopropyl-4,5-dimethylimidazoline-2-ylidene,  $(C_3N_2Me_2^iPr_2)$ , or 1,3,4,5-tetramethylimidazolin-2-ylidene,  $(C_3N_2Me_4)$ , in toluene with formation of  $Cp^*_2Sm(C_3N_2Me_2^iPr_2)$  (Figure 96a),<sup>119</sup> and  $Cp^*_2Sm(C_3N_2Me_4)_2$ , respectively. Related 1,3-dimethylimidazoline-2-ylidene,  $(C_3N_2H_2Me_2)$ , adducts of divalent lanthanidocenes  $(C_5Me_4Et)_2Ln(C_3N_2H_2Me_2)$  (Ln = Sm, Yb),  $Cp^*_2Yb(C_3N_2H_2Me_2)$  and  $(C_5H_3^tBu)_2Yb(C_3N_2H_2Me_2)$  were prepared analogously. The analogous silylene complex  $Cp^*_2Sm[SiN^tBuCHCHN^tBu]$  has been synthesized by reaction of  $Cp^*_2Sm$  with 1,3-di-*tert*-butyl-2,3-dihydro-1H-1,3,2-diazasilol-2-ylidene in toluene. The silylene ligand is

**Figure 96** (a)  $Cp^*_2Sm(C_3N_2Me_2^iPr_2)$ , (b)  $Cp^*_2Sm[SiN^tBuCHCHN^tBu]$

located asymmetrically in the metallocene wedge with one *t*Bu group much closer to the metal than the other one (Figure 96b).<sup>120</sup>

Several heterometallic lanthanide(II)/transition metal complexes have been synthesized.  $(THF)_2Yb(C_5H_4PPh_2)_2-PtMe_2$  was prepared by the reaction of  $(C_5H_4PPh_2)_2Yb(THF)$  with (*cis,cis*-1,5-cyclooctadiene)dimethylplatinum in toluene. Similar reaction with  $W(CO)_6$  in THF yields  $[(THF)_3Yb(C_5H_4PPh_2)_2W(CO)_4]$ , while  $[(THF)Yb(C_5H_4PPh_2)_2(\mu-OC)W(CO)_3]$  (Figure 97a) is obtained in toluene. In both molecules, the  $(\eta^5-C_5H_4PPh_2)_2Yb$  units are bonded to W through the P atoms giving an octahedral *cis*- $W(CO)_4P_2$  arrangement. An isocarbonyl linkage ( $W-C=O-Yb$ ) is found in  $[(THF)Yb(C_5H_4PPh_2)_2(\mu-OC)W(CO)_3]$ .<sup>121</sup> The reaction of  $Cp^*_2Yb$  with  $(dippe)PtMe_2$  (*dippe* =  $^iPr_2P(CH_2)_2P^iPr_2$ ) results in the formation of  $(dippe)Pt(\mu-Me)_2YbCp^*_2$  with

**Figure 97** (a)  $[(THF)Yb(C_5H_4PPh_2)_2(\mu-OC)W(CO)_3]$ , (b)  $(dippe)Pt(\mu-Me)(\mu-H)YbCp^*_2$

two Me groups bridging Pt and Yb. The solid-state structure of the adduct  $(\text{dippe})\text{Pt}(\mu\text{-Me})(\mu\text{-H})\text{YbCp}^*_2$  (Figure 97b), which has been prepared analogously, showed an asymmetric  $(\mu\text{-Me})(\mu\text{-H})$  bridge between both metal atoms.

Mixed-ligand complexes  $\text{CpLnCp}'$  are also known, for example,  $[\text{C}_5\text{H}_2(\text{SiMe}_3)_3][\text{C}_5\text{H}_3(\text{SiMe}_3)_2]\text{Sm}(\text{THF})$  and  $(\text{C}_5\text{H}_3^t\text{Bu}_2)(\text{Cp}^*)\text{Yb}(\text{THF})$  as bent sandwiches.

Reduction of dimethylfulvene with activated Sm or Yb in THF results in the formation of *ansa*-lanthanidocene complexes  $\text{Me}_2\text{C}(\text{C}_5\text{H}_4)_2\text{Ln}(\text{THF})_2$  (equation 23) and  $[(\text{C}_5\text{H}_2^t\text{Bu}_2\text{-C}_5\text{H}_2^t\text{Bu}_2)\text{Yb}(\text{THF})]_2$  (Figure 98), and the analogous Sm derivative are formed by an electron-transfer reaction of Yb and Sm powder with tetra(*tert*-butyl)pentafulvalene in the presence of  $\text{HgCl}_2$  in THF.

*ansa*-Metallocene complexes with oxygen bridged Cp ligands  $\text{O}(\text{CH}_2\text{CH}_2\text{C}_5\text{H}_4)_2\text{Ln}(\text{THF})_2$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) were synthesized by reduction of  $\text{O}(\text{CH}_2\text{CH}_2\text{C}_5\text{H}_4)_2\text{LnCl}$  with Na metal in THF. Divalent samarium complexes with variously substituted  $\text{Me}_2\text{Si}$ -bridged *ansa*-bis(cyclopentadienyl) ligands were prepared and structurally characterized, for example, *rac*- $\text{Me}_2\text{Si}(2\text{-Me}_3\text{Si-4-}^t\text{BuC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$  (Figure 99a), *rac*- $\text{Me}_2\text{Si}(2\text{-Me}_3\text{Si-4-}^t\text{BuMe}_2\text{SiC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$ , *meso*- $[1,2\text{-(Me}_2\text{Si)(Me}_2\text{SiOSiMe}_2)](3\text{-}^t\text{BuC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$ , and the  $\text{C}_{2v}$  symmetric  $[1,2\text{-(Me}_2\text{SiOSiMe}_2)_2](3\text{-}^t\text{BuC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$  (Figure 99b). They show high activity for the polymerization of ethylene and 1-olefins such as 1-pentene and 1-hexene. *rac*- $\text{Me}_2\text{Si}(2\text{-Me}_3\text{Si-4-}^t\text{BuMe}_2\text{SiC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$

Figure 98  $[(\text{C}_5\text{H}_2^t\text{Bu}_2\text{-C}_5\text{H}_2^t\text{Bu}_2)\text{Yb}(\text{THF})]_2$

Figure 99 (a)  $\text{Me}_2\text{Si}(2\text{-Me}_3\text{Si-4-}^t\text{BuC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$ , (b)  $[1,2\text{-(Me}_2\text{SiOSiMe}_2)_2](3\text{-}^t\text{BuC}_5\text{H}_2)_2\text{Sm}(\text{THF})_2$

induces the cyclopolymerization of 1,5-hexadiene yielding poly(methylene-1,3-cyclopentane).

The X-ray crystal structure of  $[\text{Cp}^*\text{Sm}(\mu\text{-I})(\text{THF})_2]_2$  shows two  $\text{Cp}^*\text{Sm}(\text{THF})_2$  moieties bridged by iodine via a planar  $\text{Sm}_2(\mu\text{-I})_2$  unit, with the  $\text{Cp}^*$  ring on one side of the plane and the THF molecules on the other one. The reaction of  $\text{YbI}_2$  with two equiv. of  $\text{Na}[\text{C}_5\text{H}_3(\text{SiMe}_3)_2]$  in boiling toluene gives  $\text{Na}[\{\text{C}_5\text{H}_3(\text{SiMe}_3)_2\}_2\text{Yb}(\mu\text{-I})]$  (Figure 100a), containing an iodine bridged anion  $[\{\text{C}_5\text{H}_3(\text{SiMe}_3)_2\}_2\text{Yb-I-Yb}\{\text{C}_5\text{H}_3(\text{SiMe}_3)_2\}_2]^-$ . An unusual cyclic hexanuclear

Figure 100 (a)  $\text{Na}\{[\text{C}_5\text{H}_3(\text{SiMe}_3)_2]_2\text{Yb}\}_2(\mu\text{-I})$ , (b)  $[\text{Yb}_6\{\text{C}_5\text{Me}_4(\text{SiMe}_2\text{Bu}^t)\}_6\text{I}_8]^{2-}$

**Figure 101** (a)  $[\text{Cp}^*\text{Sm}(\text{OAr})(\mu\text{-Cp}^*)\text{K}(\text{THF})_2]_\infty$ , (b)  $[\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\mu\text{-C}_5\text{Me}_4)\text{K}(\text{THF})_2\text{Sm}(\text{OAr})]_\infty$

$\text{Yb}(\text{II})$  octaiodo dianion  $[\text{Yb}_6(\eta^5\text{-Cp}')_6\text{I}_8]^{2-}$  has been prepared by reaction of one equivalent of  $\text{LiCp}'$  [ $\text{Cp}' = \text{C}_5\text{Me}_4(\text{SiMe}_2\text{Bu}')]$  with  $\text{YbI}_2$  (Figure 100b).

Reaction of  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  with one equiv. of  $\text{ArOH}$  ( $\text{Ar} = \text{C}_6\text{H}_2'\text{Bu}_2\text{-2,6-R-4}$ ,  $\text{R} = \text{H, Me, } t\text{Bu}$ ) produces unsolvated dimeric  $\text{Sm}(\text{II})$  complexes  $[\text{Cp}^*\text{Sm}(\mu\text{-OAr})_2]$ . Addition of four equiv. of HMPA to a THF solution of those complexes affords the corresponding HMPA-coordinated monomeric complexes  $\text{Cp}^*\text{Sm}(\text{OAr})(\text{HMPA})_2$ . The reaction with two equiv. of  $\text{KCp}^*$  in THF yields polymeric  $\text{Sm}(\text{II})$  complexes  $[\text{Cp}^*\text{Sm}(\text{OAr})(\mu\text{-}\eta^5\text{-Cp}^*)\text{K}(\text{THF})_2]_\infty$  (Figure 101a) in which the ' $\text{Cp}^*\text{K}(\text{THF})_2$ ' unit acts as a neutral coordinating ligand. Analogous complexes  $[\text{Cp}^*\text{Sm}(\text{XR})(\mu\text{-Cp}^*)\text{K}(\text{THF})_n]_\infty$  ( $n = 1$  or  $2$ ;  $\text{XR} = \text{OC}_6\text{H}_3'\text{Pr}_2\text{-2,6}$ ,  $\text{SC}_6\text{H}_2'\text{Pr}_3\text{-2,4,6}$ ,  $\text{NHC}_6\text{H}_2'\text{Bu}_3\text{-2,4,6}$ , or  $\text{N}(\text{SiMe}_3)_2$ ) have been synthesized in the same manner from  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$  and  $\text{KXR}$ . Using  $\text{NaN}(\text{SiMe}_3)_2$  instead of  $\text{KN}(\text{SiMe}_3)_2$  affords the ' $\text{C}_5\text{Me}_5\text{Na}(\text{THF})_3$ '-coordinated, 'monomeric'  $\text{Ln}(\text{II})$  complexes  $\text{Cp}^*\text{Ln}(\text{N}(\text{SiMe}_3)_2)(\mu\text{-Cp}^*)\text{-Na}(\text{THF})_3$  ( $\text{Ln} = \text{Sm, Yb}$ ). The reaction of  $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)_2\text{-Sm}(\text{THF})_2$  with one equiv. of  $\text{KOAr}$  in THF yields  $[\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\mu\text{-C}_5\text{Me}_4)\text{K}(\text{THF})_n\text{Sm}(\text{OAr})]_\infty$  (Figure 101b) ( $\text{Ar} = \text{C}_6\text{H}_2'\text{Bu}_2\text{-2,6-Me-4}$ ,  $n = 2$ ; or  $\text{C}_6\text{H}_3'\text{Bu}_2\text{-2,6}$ ,  $n = 1$ ), which can be viewed as a  $\text{C}_5\text{Me}_4/\text{OAr}$ -ligated  $\text{Sm}(\text{II})$  species coordinated by the silyl-linked neutral ' $\text{C}_5\text{Me}_4\text{K}$ ' ligand.

Reaction of  $[\text{Cp}^*_2\text{Yb}(\mu\text{-I})(\text{THF})_2]_2$  with  $\text{K}[\text{N}(\text{SiMe}_3)_2]$  generates  $\text{Cp}^*\text{Yb}[\text{N}(\text{SiMe}_3)_2](\text{THF})_2$  that crystallizes from toluene with a distorted piano stool (see *Piano Stool Structure*) geometry<sup>122</sup> and addition of  $\text{LnI}_2(\text{THF})_2$  ( $\text{Ln} = \text{Sm, Yb}$ ) to  $[\text{Me}_2\text{Si}(\text{tacn})\text{C}_5\text{Me}_4]\text{K}$  ( $\text{tacn} = 1,4\text{-diisopropyl-1,4,7-triazacyclononane}$ ) in THF yields monomeric solvent-free

**Figure 102**  $[\text{Me}_2\text{Si}(\text{tacn})\text{C}_5\text{Me}_4]\text{LnI}$

$[\text{Me}_2\text{Si}(\text{tacn})\text{C}_5\text{Me}_4]\text{SmI}$  and  $[\text{Me}_2\text{Si}(\text{tacn})\text{C}_5\text{Me}_4]\text{YbI}$ , in which all three N atoms of the triazacycle are coordinated to the metal (Figure 102).<sup>123</sup>

Structurally related  $\text{Ln}(\text{II})$  alkyl complexes  $[\text{Cp}^*\text{Ln}(\text{CH}(\text{SiMe}_3)_2)\text{Cp}^*\text{K}(\text{THF})_2]_\infty$  ( $\text{Ln} = \text{Sm, Eu, Yb}$ ) were prepared by reactions of  $\text{Cp}^*_2\text{Ln}(\text{THF})_2$  with one equiv. of  $\text{K}[\text{CH}(\text{SiMe}_3)_2]$  in THF. In the presence of  $\text{PhSiH}_3$ ,  $[\text{Cp}^*\text{Ln}(\text{SiH}_3)\text{Cp}^*\text{K}(\text{THF})_2]_\infty$  ( $\text{Ln} = \text{Sm, Eu, Yb}$ ) are also isolated.  $[\text{Cp}^*\text{Sm}(\text{CH}(\text{SiMe}_3)_2)\text{Cp}^*\text{K}(\text{THF})_2]_\infty$  catalyzes the polymerization of ethylene and styrene.<sup>124</sup>  $\text{Cp}^*_2\text{Yb}$  can coordinate saturated hydrocarbons as in  $\text{Cp}^*_2\text{Yb}(\mu\text{-Me})\text{BeCp}^*$  (Figure 103a). The positions of the hydrogens on the bridging methyl group show that this is not a methyl bridge having a three-center-two-electron bond between  $\text{Yb-C-Be}$ . In contrast, trialkylaluminum forms  $\text{Sm}(\text{III})$  complexes, for example,  $[(\text{C}_5\text{Me}_4\text{Et})_2\text{Sm}(\mu\text{-Me})_2\text{AlMe}_2]_2$  (Figure 103b) in which Sm and Al are bridged by  $\text{Sm-Me-Al}$  three-center-two-electron bonds.

The use of crown ethers (see *Crown Ethers*) in organolanthanide chemistry often results in formation of solvent

**Figure 103** (a)  $\text{Cp}^*_2\text{Yb}(\mu\text{-Me})\text{BeCp}^*$ , (b)  $[(\text{C}_5\text{Me}_4\text{Et})_2\text{Sm}(\mu\text{-Me})_2\text{AlMe}_2]_2$

**Figure 104**  $[\{C_5H_3(SiMe_3)_2\}Sm([18]\text{-crown-6})][Sm\{C_5H_3(SiMe_3)_2\}_3]$

**Figure 105** (a)  $[CpV(C_{10}H_8)Ln(\mu\text{-Cp})(THF)]_\infty$ , (b)  $[CpV(C_{10}H_8)]_2Ln(THF)(DME)$

separated ion pairs, like by treatment of  $Ln[C_5H_3(SiMe_3)_2]_2$  ( $Ln = Sm, Yb$ ) with [18]-crown-6 in benzene, yielding  $[\{C_5H_3(SiMe_3)_2\}Sm([18]\text{-crown-6})][Sm\{C_5H_3(SiMe_3)_2\}_3]$  (Figure 104) and  $[\{C_5H_3(SiMe_3)_2\}Yb([18]\text{-crown-6})][C_5H_3(SiMe_3)_2]$ . Reduction of  $[\{C_5H_3(SiMe_3)_2\}Sm([18]\text{-crown-6})][Sm\{C_5H_3(SiMe_3)_2\}_3]$  with K in toluene affords  $[K([18]\text{-crown-6})(\eta^2\text{-PhMe})_2][Sm\{C_5H_3(SiMe_3)_2\}_3]$ .

Reduction of  $Cp_2V$  with an excess of  $(C_{10}H_8)Yb(THF)_2$  in THF generates polymeric two-dimensional multidecker complexes  $[CpV(C_{10}H_8)Ln(\mu\text{-Cp})(THF)]_\infty$ , which are also formed from the reaction of  $YbI_2(THF)_2$  with an equimolar mixture of  $KCp$  and  $K[CpV(C_{10}H_8)]$  in THF. The analogous Eu derivative has been prepared similarly using  $EuI_2$ . The crystals consist of infinite zigzag chains formed by  $(\eta^5\text{-Cp})Ln$  ( $Ln = Eu, Yb$ ) moieties. Each Ln atom is  $\eta^2$  coordinated by  $(\eta^5\text{-Cp})V(\eta^6\text{-C}_{10}H_8)$  anions via naphthalene (Figure 105a). Reaction of  $LnI_2$  ( $Ln = Eu, Sm$ ) with an equimolar mixture of  $KCp$  and  $K[CpV(C_{10}H_8)]$  in DME forms bimetallic complexes  $[CpV(C_{10}H_8)]_2Ln(THF)(DME)$  ( $Ln = Eu, Sm$ ) containing  $CpV(C_{10}H_8)$  units  $\eta^6$ -bonded to the lanthanide (Figure 105b).

A number of mono- and bis(cyclopentadienyl)lanthanide(II) complexes with donor-functionalized Cp ligands has been reported.  $(MeOCH_2CH_2C_5H_4)_2Sm$  and  $(MeOCH_2CH_2C_5H_4)_2Yb$  were synthesized by the reaction of  $K[C_5H_4CH_2CH_2OMe]$  with  $LnI_2$  ( $Ln = Sm, Yb$ ).

Recrystallization of the Yb complex from THF produces the solvated  $(MeOCH_2CH_2C_5H_4)_2Yb(THF)$  with coordination number 9 at Yb. Optically active metallocene complexes of Sm(II) and Yb(II) containing cyclopentadienyl systems with chiral N- or O-substituted side chains as ligands are available by reaction of the Na or K salts of the ligands with  $LnI_2$ , for example,  $[Ln\{(S)\text{-}\eta^5\text{:}\eta^1\text{-}C_5H_4(CH_2CHROMe)_2\}]$  ( $R = Me, Ph$ ;  $Ln = Sm, Yb$ ),  $[Ln\{(S)\text{-}\eta^5\text{:}\eta^1\text{-}C_5H_4(CH_2CHMeNMe_2)_2\}]$  ( $Ln = Sm, Yb$ ) (Figure 106a),  $[Ln\{(S)\text{-}\eta^5\text{:}\eta^1\text{-}C_5H_4(CHPhCH_2NMe_2)_2\}]$  ( $Ln = Sm, Yb$ ),  $[C_5H_4(CMe_2CH_2C_5H_4N\text{-}2)]_2Yb$ , and  $[C_5H_3(SiMe_3)(CMe_2CH_2C_5H_4N\text{-}3)]_2Yb$  (Figure 106b).

**Figure 106** (a)  $[Ln(S)\text{-}\eta^5\text{:}\eta^1\text{-}C_5H_4(CH_2CHMeNMe_2)_2]_2$ , (b)  $[C_5H_3(SiMe_3)(CMe_2CH_2C_5H_4N\text{-}3)]_2Yb$

**Figure 107** (a)  $(C_5H_3(CH_2CH_2NMe_2)_2-1,2)YbI(THF)_2$ , (b)  $(C_5H_3(CH_2CH_2NMe_2)_2-1,2)Yb(C_5H_4^tBu)$

Analogous reactions of a mixture of the potassium salts of 1,2- and 1,3-bis[(dimethylamino)ethyl]cyclopentadiene with equimolar amounts of  $YbI_2$  in THF allows only the isolation of crystalline  $(\eta^5:\eta^1:\eta^1-C_5H_3(CH_2CH_2NMe_2)_2-1,2)YbI(THF)_2$  (Figure 107a). The reaction of this half-sandwich complex with  $KCp^*$  and  $NaC_5H_4^tBu$  results in the formation of  $(\eta^5:\eta^1:\eta^1-C_5H_3(CH_2CH_2NMe_2)_2-1,2)Yb(\eta^5-C_5H_4^tBu)$  (Figure 107b) and  $(\eta^5:\eta^1:\eta^1-C_5H_3-(CH_2CH_2NMe_2)_2-1,2)Yb(Cp^*)$  respectively.<sup>83</sup>

Linked cyclopentadienyl-anilido or amido lanthanide(II) complexes  $Me_2Si(C_5Me_4)(NPh)Ln(THF)_n$  ( $Ln = Yb, n = 3$ ;  $Ln = Sm, n = 0-1$ ) are prepared from  $Ln[N(SiMe_3)_2]_2(THF)_2$  with 1 equiv. of  $(C_5Me_4H)SiMe_2NPh$ . Recrystallization of  $Me_2Si(C_5Me_4)(NPh)Yb(THF)_3$  from toluene/hexane yields  $[Me_2Si(C_5Me_4)(NPh)Yb(THF)]_2$  as a dimer through an 'intermolecular'  $Yb-Ph$   $\pi$ -interaction (Figure 108a).  $Me_2Si(C_5Me_4)(NPh)Yb(THF)_3$  is oxidized in the presence of azobenzene or fluorenone yielding the Yb(III) complexes  $Me_2Si(C_5Me_4)(NPh)Yb(THF)(\mu_2-\eta^2:\eta^3-N_2Ph_2)Yb(NPh)(C_5Me_4)SiMe_2$  and  $Me_2Si(C_5Me_4)(NPh)Yb(THF)_2(OC_{13}H_8)$  respectively.<sup>125</sup> A tetranuclear Yb(II) complex with both alkoxy and ether functionalities in the Cp side chain  $\{[(\eta^5-C_5H_4)CH_2CH(\mu^3:\eta^1-O)CH_2O^tBu]Yb\}_4$  was synthesized by the reaction of the potassium salt of the corresponding ligand and  $YbI_2(THF)_2$ . Redox transmetalation reaction of this complex with  $Me_2Hg$  yields the Yb(III) complex  $[(\eta^5-C_5H_4)CH_2CH(\eta^1-O)CH_2O^tBu]YbMe(THF)$ .<sup>126</sup> The dimeric Yb(II) half-sandwich complex  $\{[(\eta^5-C_5Me_4)SiMe_2OSiMe_2(\eta^1-O)]-$

$Yb(THF)_2\}$  (Figure 108b) containing the heterobifunctional tetramethylcyclopentadienyl-silanolate ligand has also been reported.

Half-sandwich (*see Half-sandwich Complexes*) indenyl complexes of Yb(II) have been prepared by reaction of  $(\mu-C_{10}H_8)[YbI(DME)_2]_2$  with indene.  $(Ind)_2YbI(DME)_2$ , is a monomer in the solid state and stable in DME solution, although it disproportionates in THF yielding  $(Ind)_2Yb(THF)_2$  and  $YbI_2(THF)_2$ .<sup>127</sup> The reaction of samarium diiodide with potassium indenide and potassium fluorenone results in the formation of  $(Ind)_2Sm(THF)_3$  (Figure 109a) and  $(Flu)_2Sm(THF)_2$  (Figure 109b), respectively. Structural data indicate that, in both compounds, Sm has a more open coordination sphere compared to  $Cp^*_2Sm(THF)_2$ .

*ansa*-Bis(indenyl) complexes  $(LCH_2CH_2L)Yb(THF)_2$  (Figure 110a) ( $L = 1$ -indenyl and 4,7-dimethylindenyl) have been prepared from  $(LCH_2CH_2L)Li_2$  and  $YbCl_3$  in  $Et_2O$  with subsequent reduction by Na metal in THF. Solvent-free racemic bis(1-(2-dimethylaminoethyl)indenyl) complexes,  $(Me_2NCH_2CH_2C_9H_6)_2Sm$  and  $(Me_2NCH_2CH_2C_9H_6)_2Yb$ , (Figure 110b) have been synthesized by the reaction of  $(Me_2NCH_2CH_2C_9H_6)K$  with  $LnI_2$  ( $Ln = Sm, Yb$ ). The nitrogen atoms of both dimethylaminoethyl groups coordinate intramolecularly to Yb.

Fluorenyl complexes of divalent ytterbium  $[(Flu)_2Yb(L)_n]$  (Figure 111a) ( $L = THF, n = 2$ ;  $L = DME, n = 1$ ;  $L = ^tBuNCHCHN^tBu, n = 1$ ) have been prepared by reaction of  $YbI_2(THF)_2$  with two equiv. of  $KFlu$  as well as

**Figure 109** (a)  $(Ind)_2Sm(THF)_3$ , (b)  $(Flu)_2Sm(THF)_2$

**Figure 108** (a)  $[Me_2Si(C_5Me_4)(NPh)Yb(THF)]_2$ , (b)  $[(C_5H_4)SiMe_2OSiMe_2(\eta^1-O)Yb(THF)]_2$

**Figure 110** (a)  $(\text{C}_9\text{H}_6\text{CH}_2\text{CH}_2\text{C}_9\text{H}_6)\text{Yb}(\text{THF})_2$ ,  
(b)  $(\text{Me}_2\text{NCH}_2\text{CH}_2\text{C}_9\text{H}_6)_2\text{Yb}$

**Figure 111** (a)  $(\text{Flu})_2\text{Yb}(\text{t-BuNCHCHNt-Bu})$ , (b) *ansa*- $\text{Me}_2\text{Si}(\text{C}_{13}\text{H}_8)_2\text{Sm}(\text{THF})_4$

by reduction of fluorene with  $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{THF})_2$  in THF. The mixed-ligand sandwich complex  $(\text{Flu})(\text{Cp}^*)\text{Yb}(\text{DME})$  results from the reaction of  $[\text{YbI}(\text{DME})_2]_2(\text{C}_{10}\text{H}_8)$  with  $\text{Cp}^*\text{H}$  and  $\text{KFlu}$  in DME. *ansa*- $\text{Me}_2\text{Si}(\text{C}_{13}\text{H}_8)_2\text{Yb}(\text{THF})$  and *ansa*- $\text{Me}_2\text{Si}(\text{C}_{13}\text{H}_8)_2\text{Sm}(\text{THF})_4$  (Figure 111b) were obtained by treatment of the appropriate Ln diiodides with  $[\text{ansa-Me}_2\text{Si}(\text{C}_{13}\text{H}_9)_2]\text{K}_2$  in THF.<sup>128</sup>

$(\text{Me}_3\text{SiC}_{13}\text{H}_8)_2\text{Sm}(\text{THF})_2$  reacts with an excess of  $\text{AlR}_3$  ( $\text{R} = \text{Me}, \text{Et}, \text{Pr}, \text{t-Bu}$ ) and  $\text{BEt}_3$  yielding  $(\text{Me}_3\text{SiC}_{13}\text{H}_8-\text{AlR}_3)_2\text{Sm}$  and  $(\text{Me}_3\text{SiC}_{13}\text{H}_8-\text{BEt}_3)_2\text{Sm}$ , respectively in a reversible equilibrium (equation 24). In contrast,  $(\text{Me}_3\text{SiC}_{13}\text{H}_8)_2\text{Yb}(\text{THF})_2$  reacts with an excess of  $\text{AlMe}_3$

yielding  $(\text{Me}_3\text{SiC}_{13}\text{H}_8)(\text{Me}_3\text{SiC}_{13}\text{H}_8-\text{AlMe}_3)\text{Yb}$ , in which, according to the X-ray crystal structure, only one  $\text{AlMe}_3$  coordinates to the Yb atom through two Me groups via an agostic interaction. One of the  $\text{Me}_3\text{Si}$ -fluorenyl groups is  $\eta^5$ -coordinated, the other one  $\eta^6$  (Figure 112). The bis(indenyl) derivative  $(\text{t-PrC}_9\text{H}_6)_2\text{Yb}(\text{THF})_2$  shows the same behavior.<sup>129</sup>

(24)

Divalent organolanthanide complexes  $\text{Ln}(\text{COT})$  ( $\text{Ln} = \text{Eu}, \text{Yb}$ ) were precipitated with COT from the metal solution in liquid ammonia.  $(\text{COT})\text{Yb}(\text{py})_3$  (Figure 113a) crystallizes as a 3-legged piano stool. Ionic sandwich complexes like  $[(\text{DME})\text{K}]_2[\text{Yb}(\text{COT})_2]$  (Figure 113b) are available in liquid ammonia by addition of a stoichiometric amount of K, Ln, and COT.

The reductive coupling (*see Reductive Coupling*) of acenaphthylene by activated metallic ytterbium and samarium yields *ansa*-lanthanidocenes  $[(\eta^5-\text{C}_{12}\text{H}_8)_2\text{Ln}(\text{THF})_2]$  ( $\text{Ln} = \text{Yb}, \text{Sm}$ ) (equation 25).

(25)

**Figure 112**  $(\text{Me}_3\text{SiC}_{13}\text{H}_8)(\text{Me}_3\text{SiC}_{13}\text{H}_8-\text{AlMe}_3)\text{Yb}$

**Figure 113** (a)  $(\text{COT})\text{Yb}(\text{py})_3$ , (b)  $[(\text{DME})\text{K}]_2[\text{Yb}(\text{COT})_2]$

**Figure 114**  $(\text{Gaz})_2\text{Yb}(\text{THF})_2$

According to X-ray crystallography and NMR data, coupling of the radical anions of acenaphthylene in these reaction occurs stereoselectively affording exclusively  $C_2$ -symmetric *rac-ansa*-lanthanidocenes.<sup>130</sup> The related  $C_2$ -symmetric *rac-ansa*-ytterbocene complex  $(\text{Gaz})_2\text{Yb}(\text{THF})_2$  ( $\text{Gaz}$  = guajazulene) (Figure 114) is isolated when  $\text{GAZ}$  is reacted with  $(\text{C}_{10}\text{H}_8)\text{Yb}(\text{THF})_2$ .<sup>131</sup>

The chemistry of the lanthanide(II) complexes with pyrrolyl and pyrazolylborate ligands is unusual and provided surprising structures and unprecedented reactivity including dinitrogen reduction. The reactions of  $\text{SmI}_2(\text{THF})_2$  and  $\text{YbI}_2(\text{THF})_2$  with the alkali metal salts of 2,5-dimethylpyrrole led to the formation of divalent mono- and polynuclear complexes, for example,  $(\mu-\eta^1:\eta^5-\text{Me}_2\text{C}_4\text{H}_2\text{N})_3\text{Sm}(\mu\text{-Cl})[\text{Li}(\text{THF})_2]_2$  (Figure 115a),  $\{[(\text{Na}(\text{THF})_2)(\mu-\eta^1:\eta^5-\text{Me}_2\text{C}_4\text{H}_2\text{N})_3\text{Sm}]_2(\mu-\eta^1:\eta^5-\text{Me}_2\text{C}_4\text{H}_2\text{N})_2(\text{THF})_2\}$ ,  $\{(\mu-\eta^1:\eta^5-\text{Me}_2\text{C}_4\text{H}_2\text{N})_2\text{Yb}(\mu\text{-Cl})[\text{Li}(\text{OEt}_2)]\}_2$ , and  $\{(\mu-\eta^1:\eta^5-\text{Me}_2\text{C}_4\text{H}_2\text{N})_4[\text{K}(\text{THF})]_2\text{Yb}\}_n$ .<sup>132</sup> The reaction of diphenylbis(2-pyrrolyl)methane with  $\text{KH}$  and subsequent treatment with  $\text{YbI}_2(\text{THF})_2$

leads to  $[\text{Ph}_2\text{C}(\text{C}_4\text{H}_3\text{N})\text{Yb}]_8$  (Figure 115b) as the major product.<sup>133</sup>

When the similar reaction has been carried out using  $\text{SmI}_2(\text{THF})_2$ , a four-electron dinitrogen reduction is achieved, yielding  $\{[\mu\text{-Ph}_2\text{C}(\eta^1:\eta^5\text{-C}_4\text{H}_3\text{N})_2]\text{Sm}\}_4(\mu\text{-}\eta^1:\eta^1:\eta^2:\eta^2\text{-N}_2)$  (Figure 116).

Reaction of  $[\text{Sm}\{\text{N}(\text{SiMe}_3)_2\}_2(\text{THF})_2]$  with one equiv. of 1,1-di( $\alpha$ -pyrrolyl)cyclohexane in THF affords dark red  $\{[\text{1,1-(}\alpha\text{-C}_4\text{H}_3\text{N)}_2\text{C}_6\text{H}_{10}]\text{Sm}\}_8(\text{THF})_4$ . It reacts rapidly with  $\text{N}_2$  to form the dinitrogen complex  $\{[(\text{CH}_2)_5\text{C}(\text{C}_4\text{H}_3\text{N})_2]\text{Sm}\}_4(\text{THF})_2(\mu\text{-N}_2)$ .<sup>134</sup>  $\text{SmCl}_3(\text{THF})_3$  reacts with 0.5 equiv. of  $(\text{Et}_8\text{-calix-pyrrole})[\text{Li}(\text{THF})_4]$  yielding  $(\text{Et}_8\text{-calix-pyrrole})\text{-Sm}_2\{(\mu\text{-Cl})_2[\text{Li}(\text{THF})_2]\}_2$ , which, by reduction with  $\text{LiAlH}_4$ ,

**Figure 116**  $\{[\mu\text{-Ph}_2\text{C}(\text{C}_4\text{H}_3\text{N})_2]\text{Sm}\}_4(\text{N}_2)$

(a)

(b)

**Figure 115** (a)  $(\mu\text{-Me}_2\text{C}_4\text{H}_2\text{N})_3\text{Sm}(\mu\text{-Cl})[\text{Li}(\text{THF})_2]_2$ , (b)  $[\text{Ph}_2\text{C}(\text{C}_4\text{H}_3\text{N})\text{Yb}]_8$

**Figure 117**  $(\text{Et}_8\text{-calix-pyrrole})\text{Sm}_2(\text{THF})_4$  (Et-groups are omitted for clarity)

produces either the mixed-valence  $(\text{Et}_8\text{-calix-pyrrole})\text{Sm}_2(\text{THF})_2(\mu\text{-Cl})_2[\text{Li}(\text{THF})_2]$  or the divalent  $(\text{Et}_8\text{-calix-pyrrole})\text{Sm}_2(\text{THF})_4$  (Figure 117), depending on the reaction conditions employed.<sup>135</sup>

Use of the sterically demanding hydrotris(3-*t*-Bu-5-Me-pyrazolyl)borate ligand ( $\text{Tp}^t\text{Bu,Me}$ ) results in monomeric  $(\text{Tp}^t\text{Bu,Me})\text{YbI}(\text{THF})$  (Figure 118), which does not disproportionate to  $\text{Yb}(\text{Tp}^t\text{Bu,Me})_2$  and  $\text{YbI}_2$ . Reaction of  $[(\text{Tp}^t\text{Bu,Me})\text{YbH}]_2$  with  $\text{C}_5\text{H}_6$  and  $\text{Me}_3\text{SiC}_5\text{H}_5$  gave the corresponding mixed-ligand complexes  $(\text{Tp}^t\text{Bu,Me})\text{Yb}(\text{C}_5\text{H}_4\text{R})$  ( $\text{R} = \text{H}, \text{SiMe}_3$ ). The solid-state structure of the  $\text{SiMe}_3$ -derivative exhibits an unusual distortion; one of the pyrazolyl rings is rotated in a way to bring both pyrazolyl nitrogens in bonding contact with Yb.<sup>136</sup>

**Figure 118**  $(\text{Tp}^t\text{Bu,Me})\text{YbI}(\text{THF})$

**Figure 119** (a)  $[\text{Yb}(\mu\text{-SPh})(\eta^5\text{-C}_4\text{Me}_4\text{P})(\text{THF})_2]_2$ , (b)  $(\text{THF})_2\text{Yb}[\mu\text{-C}_4\text{Me}_4\text{P}]_2\text{Ru}(\text{H})_2(\text{PPh}_3)_2$

Bis( $\eta^5$ -phospholyl) or bis( $\eta^5$ -arsolyl) complexes of Sm or Yb have been prepared from the metal or by metathesis from the metal iodides (equation 26). The coordinated THF molecules can be removed by heating a toluene solution in vacuo, in the case of the 2,3,4,5-tetramethylphospholyl or arsolyl, but not with the 2,5-diphenylphospholyl complexes.

(26)

Related complexes  $[\text{Yb}(\mu\text{-Cl})(\eta^5\text{-C}_4\text{Me}_4\text{P})(\text{THF})_2]_2$  and  $[\text{Yb}(\mu\text{-SPh})(\eta^5\text{-C}_4\text{Me}_4\text{P})(\text{THF})_2]_2$  (Figure 119a) were prepared by direct cleavage of the P–Cl or P–S bonds of respective 1-chloro- and 1-phenylthio-2,3,4,5-tetramethylphosphole by ytterbium metal in THF at room temperature. Reaction of bis( $\eta^5$ -tetramethylphospholyl)ytterbium(II) with  $\text{RuH}_4(\text{PPh}_3)_3$  afforded heterometallic  $(\text{THF})_2\text{Yb}[\mu\text{-}\eta^5\text{:}\eta^1\text{-C}_4\text{Me}_4\text{P}]_2\text{Ru}(\text{H})_2(\text{PPh}_3)_2$  (Figure 119b).

Carboranyl complexes of  $\text{Ln}(\text{II})$  like  $[\text{Me}_2\text{Si}(\text{C}_2\text{B}_{10}\text{H}_{11})(\text{Cp})]\text{Sm}(\text{THF})_2$  are prepared by reaction of  $\text{SmI}_2$  with 2 equiv. of  $[\text{Me}_2\text{Si}(\text{C}_2\text{B}_{10}\text{H}_{11})(\text{Cp})]\text{Na}$  in THF. In contrast, the reaction with  $\text{YbI}_2$  afforded  $[\text{Me}_2\text{Si}(\text{C}_2\text{B}_{10}\text{H}_{11})(\text{Cp})]_2\text{Yb}(\text{THF})_2$  (Figure 120a). Treatment of  $\text{LnI}_2$  with 1 equiv. of  $\text{K}_2[(\text{PhCH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}]$  in THF yields after recrystallization from DME monomeric *exo-nido*- $[(\text{PhCH}_2)_2\text{C}_2\text{B}_{10}\text{H}_{10}]\text{Ln}(\text{DME})_3$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ). Using two equiv. of  $\text{Na}_2[(\text{PhCH}_2)_2\text{C}_2\text{B}_9\text{H}_9]$  results in dimeric complexes  $[\text{exo-nido}\{(\text{PhCH}_2)_2\text{C}_2\text{B}_9\text{H}_9\}\text{Ln}(\text{THF})_3]_2$  ( $\text{Ln} = \text{Sm}, \text{Yb}$ ) (Figure 120b).

Carboranyl/indenyl complexes of  $\text{Yb}(\text{II})$  are formed by treatment of  $\text{YbI}_2$  with  $\text{Na}[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]$ , resulting in  $[\{\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})\}\text{Yb}(\mu\text{-I})(\text{THF})_2]_2$  (Figure 121a), which reacts with  $\text{NaH}$  yielding  $[\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\sigma\text{-C}_2\text{B}_{10}\text{H}_{10})]\text{Yb}(\text{THF})_3$ . Treatment with  $\text{Na}[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]$  in THF gave  $[\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Yb}(\text{THF})[\text{Me}_2\text{Si}(\mu\text{-}\eta^5\text{-Ind})(\sigma\text{-C}_2\text{B}_{10}\text{H}_{10})]\text{Na}(\text{THF})_3$  (Figure 121b), which is also formed from  $\text{YbI}_2$  and two equiv.

**Figure 120** (a)  $[\text{Me}_2\text{Si}(\text{C}_2\text{B}_{10}\text{H}_{11})(\text{Cp})]_2\text{Yb}(\text{THF})_2$ , (b)  $[\text{exo-nido-}\{(\text{PhCH}_2)_2\text{C}_2\text{B}_9\text{H}_9\}\text{Ln}(\text{THF})_3]_2$  (Ln = Sm, Yb)

**Figure 121** (a)  $[\{\text{Me}_2\text{Si}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{11})\}\text{Yb}(\mu\text{-I})(\text{THF})_2]_2$ , (b)  $[\text{Me}_2\text{Si}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Yb}(\text{THF})[\text{Me}_2\text{Si}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{11})]\text{Na}(\text{THF})_3$

of  $\text{Na}[\text{Me}_2\text{Si}(\text{Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]$  in THF and reaction with NaH via intermediate  $[\text{Me}_2\text{Si}(\eta^5\text{-Ind})(\text{C}_2\text{B}_{10}\text{H}_{11})]_2\text{Yb}(\text{THF})_2$ .

Divalent  $[1,3\text{-bis}(\text{trimethylsilyl})\text{propenyl}]_2\text{Sm}(\text{THF})_2$  (Figure 122) and  $[1,3\text{-diphenylpropenyl}]_2\text{Sm}(\text{THF})_2$  were synthesized by the reaction of potassium 1,3-bis(trimethylsilyl)propenide or potassium 1,3-diphenylpropenide with  $\text{SmI}_2$ .

Organometallic compounds of lanthanide metals other than Sm, Eu, and Yb are very rare until now. But the development of this chemistry became possible after the synthesis of divalent precursors of Tm, Dy, and Nd in the late 1990s, namely of their diiodides (see *Scandium, Yttrium & the Lanthanides: Inorganic & Coordination Chemistry*) and by using ligands such as phospholyl or arsolyl, which stabilize divalent lanthanide ions.

The first organothulium(II) compound  $(\eta^5\text{-}1,3\text{-(Me}_3\text{Si)}_2\text{-C}_5\text{H}_3)_2\text{Tm}(\text{THF})$  (Figure 123a) was synthesized from  $\text{K}[\text{C}_5\text{H}_3(\text{SiMe}_3)_2\text{-}1,3]$  and  $\text{TmI}_2(\text{THF})_3$  in  $\text{Et}_2\text{O}$  or THF in Ar atmosphere. In contrast,  $\text{DyI}_2$  and  $\text{TmI}_2$  react with  $\text{K}[\text{C}_5\text{H}_3(\text{SiMe}_3)_2\text{-}1,3]$  under  $\text{N}_2$  with reduction of  $\text{N}_2$ , yielding Ln(III) complexes like  $[\{\eta^5\text{-}1,3\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_3\}_2\text{Dy}]_2(\mu\text{-N}_2)$ .<sup>137</sup>  $\text{TmI}_2(\text{THF})_3$  reacts with  $\text{K}(\text{L})$  ( $\text{L} = 2, 5\text{-bis}(\text{trimethylsilyl})\text{-}3,4\text{-dimethylphospholide}$  or  $\text{-arsolide}$ ;  $2,5\text{-di-tert-butyl-}3,4\text{-dimethylphospholide}$ ) forming the corresponding  $[\eta^5\text{-PC}_4\text{Me}_2(\text{SiMe}_3)_2]_2\text{Tm}(\text{THF})$ ,  $[\eta^5\text{-AsC}_4\text{Me}_2(\text{SiMe}_3)_2]_2\text{Tm}(\text{THF})$  (Figure 123b), and  $[\eta^5\text{-PC}_4\text{Me}_2(\text{tBu})_2]_2\text{Tm}(\text{THF})$ .<sup>138</sup>

The first example of a subvalent organolanthanum complex,  $[\text{K}([18]\text{crown-}6)(\eta^2\text{-C}_6\text{H}_6)_2][\text{La}\{\text{C}_5\text{H}_3(\text{tBu})_2\text{-}1,3\}_2]_2(\mu\text{-C}_6\text{H}_6)$  was prepared by reduction of  $\text{La}[\text{C}_5\text{H}_3\text{tBu}_2]_3$  with K in the presence of 18-crown-6 in benzene. The anion

Figure 122  $[1,3\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_3]_2\text{Sm}(\text{THF})_2$

Figure 123 (a)  $(1,3\text{-(Me}_3\text{Si)}_2\text{C}_5\text{H}_3)_2\text{Tm}(\text{THF})$ , (b)  $[\text{AsC}_4\text{Me}_2(\text{SiMe}_3)_2]_2\text{Tm}(\text{THF})$

of this compound contains two  $[\text{C}_5\text{H}_3\text{tBu}_2]_2\text{La}(\text{II})$  moieties bridged by an  $\eta^6\text{:}\eta^6\text{-benzenide}$  monoanionic ligand (Figure 124). An alternative formulation of the anion with two  $[\text{C}_5\text{H}_3\text{tBu}_2]_2\text{La}(\text{III})$  moieties bridged by an  $[\eta^6\text{-C}_6\text{H}_6]^{3-}$  seems less plausible.

### 11.3.3 Divalent Lanthanidocenes as Reducing Agents

Divalent organolanthanides, especially  $\text{Cp}^*_2\text{Sm}(\text{THF})_2$ , are widely used as reducing agents.<sup>114</sup> Decamethylsamarocene reduces a number of organic and inorganic substrates by one-electron transfer to give Sm(III) species, for example, as shown in equation (27).<sup>139</sup>

Divalent ytterbium has a lower reduction potential. Therefore, Yb(II) complexes reduce only substrates with relatively high electron affinity. That could be demonstrated by the isolation of several adducts between heterocyclic nitrogen bases and  $\text{Cp}^*_2\text{Yb}$ . 1:1-Adducts of the type  $\text{Cp}^*_2\text{Yb}(\text{L})$  are formed with pyrazine, quinoxaline, 1,5- and 1,8-naphthyridine, 4,4'-bipyridine, phthalazine, and azobenzene. The adducts are paramagnetic, and their effective magnetic moments are consistent with the formulation  $\text{Cp}^*_2\text{Yb}^{3+}(\text{L}^{\cdot-})$  ( $\text{L}^{\cdot-}$  = radical anion), in which spins on the individual units are uncoupled down to 5 K.  $\text{Cp}^*_2\text{Yb}$  and pyridazine, phenazine, 2,2'-azopyridine, 2,2'-bipyrimidine, 2,2'-azobenzene, and 2,3-bis(2-pyridino)quinoxaline form  $(\text{Cp}^*_2\text{Yb})_2(\mu\text{-L})$  adducts. The crystal structure of  $(\text{Cp}^*_2\text{Yb})_2(\mu\text{-bipyrimidine})$  shows that two metallocenes are bridged by a planar bipyrimidine ligand. The effective magnetic moment of these 2:1 adducts shows that each  $[\text{Cp}^*_2\text{Yb}(\text{III})]$  fragment behaves as an isolated paramagnet; the bridging ligand is a diamagnetic dianion.<sup>140</sup> The 2,2'-bipyridyl and 1,3-diazadiene adducts  $\text{Cp}^*_2\text{Yb}(\text{bipy})$

## 1 INTRODUCTION

Selenium is the first member of the group 16 elements O, S, Se, Te, and Po that shows some metallic character. Among the several modifications of selenium, three nonmetallic ones contain  $\text{Se}_8$  rings, whereas at least two others (gray metallic and amorphous black selenium) are semiconductors. Much of the current interest in the different allotropic modifications of selenium is connected with its extensive use in semiconductor applications, namely, in photocells, in xerography, and in rectifiers. Nanomaterials containing selenium are also becoming important targets. Selenium (and also tellurium) shares with sulfur the tendency to form homonuclear catenation in the element as well as in compound formation. The increasing metallic character in the series O, S, Se, Te, Po is reflected also in the lower electronegativity, in the less acid character of the oxides, and in the lower stability of the oxidation number +VI for selenium compared to sulfur.

Apart from the simple hydrogen chalcogenides of Se and Te (which are more acid and thermally less stable than the corresponding sulfur analogs) the most stable inorganic compounds of selenium (and its higher homologs) are: (1) the various chalcogenides and polychalcogenides with strongly positive counterions such as the alkali metals or the alkaline-earth metals, and those that are more covalently bonded to various transition metals; (2) a large variety of compounds of  $\text{Se}^{\text{II}}$ ,  $\text{Se}^{\text{IV}}$ , and  $\text{Se}^{\text{VI}}$  with the electronegative elements O, F, Cl, and Br; (3) a number of homologous compounds belonging to the interesting class of sulfur–nitrogen compounds; and (4) a class of organoselenium compounds with other ligands such as

Cl or Br as secondary ligands. All are somewhat less stable than the corresponding sulfur compounds. The tendency to form double bonds is smaller in selenium than sulfur, although the existence of strong  $\text{Se}=\text{O}$  bonds in oxo–halo selenium compounds such as  $\text{SeOCl}_2$  or  $[\text{SeOCl}_4]^{2-}$  indicate the ability to form significant (p–d) $\pi$  bonding, quite in contrast to tellurium.

A well-known feature in the redox chemistry of selenium is its anomalous difficulty in attaining the highest oxidation number +VI. It shares this feature with its neighbors Ge, As, and Br, which immediately follow the 3d metals in the periodic table. The structural aspects and stereochemistry of selenium chemistry are quite diverse. In addition to normal two-valent geometries with bent coordination around the central Se (e.g.  $\text{H}_2\text{Se}$ ,  $\text{SeCl}_2$ ,  $\text{Se}_2\text{Cl}_2$ ), the following are known: three-coordinate pyramidal  $\text{Se}^{\text{IV}}$  compounds (e.g.  $\text{H}_2\text{SeO}_3$ ,  $\text{SeCl}_3^+$  in  $\text{SeCl}_4$ , polymeric  $\text{SeO}_2$ ); four-coordinate 10-electron systems with  $\psi$ -trigonal bipyramidal coordination (e.g.  $\text{SeF}_4$ ); five-coordinate 12-electron systems with  $\psi$ -octahedral coordination (e.g.  $[\text{SeOCl}_4]^{2-}$ ); and hypervalent octahedral (distorted and undistorted, see below) coordination (e.g.  $[\text{SeCl}_6]^{2-}$ ,  $[\text{SeBr}_6]^{2-}$ ). The additional ability to form higher coordination with hypervalent bonding (described here as systems of three-center four-electron bonds, as in the hexahaloselenates) leads to many variations of intermolecular aggregation in the solid state, as exemplified by the cubane-like tetranuclear halides  $[\text{SeCl}_4]_4$  and  $[\text{SeBr}_4]_4$ .

The present account will concentrate on the basic inorganic chemistry of inorganic selenium that will be useful to a reader or researcher exploring this subject for the first time. Thus, the review will describe the diverse range of cations oxo- and halo-compounds that selenium forms.

Other areas of selenium chemistry, such as selenium rings,<sup>1,2</sup> selenides,<sup>3,4</sup> organoselenium compounds,<sup>5–7</sup> and the focus of older, more comprehensive accounts of Se halide chemistry<sup>8,9</sup> will not be covered here. Additionally, the vast environmental chemistry of selenium, for example, its aqueous<sup>10</sup> and sediment<sup>11</sup> speciation,<sup>12</sup> plant uptake,<sup>13,14</sup> nutritional<sup>15</sup> and human health<sup>16,17</sup> aspects, and appearance in coal<sup>18</sup> and coal-derived ash,<sup>19,20</sup> are beyond the scope of this review. The previous reviews on Se-containing ligands,<sup>21–24</sup> biochemistry of selenium,<sup>25</sup> as well as other relevant aspects,<sup>26,27</sup> remain some of the most valuable sources for information on these subjects.

## 2 POLYATOMIC CATIONS

### 2.1 Homocyclic Selenium Cations

Several types of homocyclic structures of selenium atoms are known. Neutral selenium rings  $\text{Se}_n$  with  $n = 5–10$  have been studied in the vapor phase by mass spectrometry. In solution,  $\text{Se}_n$  species with  $n = 6–8$  have been observed by HPLC techniques. The crystal structure of  $\text{Se}_6$  and three modifications of  $\text{Se}_8$  have been determined by X-ray diffraction.<sup>1,2</sup>

It has been found that selenium may be oxidized by several different oxidizing agents to a variety of polyatomic cations. In 1827, Magnus observed that sulfuric acid dissolved selenium to give green or yellow solutions.<sup>28</sup> It has been shown that these solutions contain the polyatomic cations  $\text{Se}_4^{2+}$  and  $\text{Se}_8^{2+}$ .<sup>29</sup>

### 2.1.1 $\text{Se}_4^{2+}$ Cation

In highly acidic and oxidizing solutions like fluorosulfuric, sulfuric, and disulfuric acids with additional oxidants like selenium dioxide, peroxydisulfuryl difluoride or  $\text{SbF}_5$ ,  $\text{Se}_4^{2+}$  salts can be prepared (see equations 1–3). The products have been characterized by cryoscopic, conductometric, and spectroscopic experiments.<sup>29,30</sup>

The yellow to orange compounds  $\text{Se}_4(\text{HS}_2\text{O}_7)_2$ ,  $\text{Se}_4(\text{S}_4\text{O}_{13})_2$ , and  $\text{Se}_4(\text{Sb}_2\text{F}_{11})_2$  have been prepared.<sup>31</sup> Crystallographic studies on  $\text{Se}_4(\text{HS}_2\text{O}_7)_2$  have shown that the cation  $\text{Se}_4^{2+}$  has square-planar ( $D_{4h}$ ) geometry.<sup>32</sup> The structure can be described by valence bond theory<sup>33</sup> in terms of four resonance structures equivalent to (1a), or by simple molecular orbital theory in which three of the four  $\pi$  molecular orbitals are filled.<sup>34</sup> The  $\text{Se}_4^{2+}$  ions are examples of six- $\pi$ -electron systems, and they are thus examples of inorganic aromatic compounds (1b).

Their  $\pi$ -bond order is 0.25; accordingly, the overall Se–Se bond length of 2.283 Å in  $\text{Se}_4(\text{HS}_2\text{O}_7)_2$ <sup>32</sup> is significantly shorter than the Se–Se distance of 2.34 Å in the  $\text{Se}_8$  molecule. The intense yellow–orange color of the  $\text{Se}_4^{2+}$  ion ( $\lambda_{\text{max}}$  410 nm,  $\epsilon$  8000) is to be expected from the dipole-allowed excitation of an electron from the highest filled  $\pi$ -orbital which is of symmetry  $e_g$  and almost nonbonding, to the lowest empty  $\pi$ -orbital ( $b_{2u}$ ). The square-planar arrangement is also consistent with magnetic circular dichroism of the  $\text{Se}_4^{2+}$  ion in solution.<sup>35</sup>

In crystals of  $\text{Se}_4(\text{Sb}_2\text{F}_4)(\text{Sb}_2\text{F}_5)(\text{SbF}_6)_5$ , prepared from Se and  $\text{SbF}_5$  in liquid  $\text{SO}_2$ , and in  $\text{Se}_4(\text{AlCl}_4)_2$ ,<sup>36,37</sup> the  $\text{Se}_4^{2+}$  ion has crystallographic inversion symmetry with average Se–Se distances of 2.260 and 2.286 Å.

Selenium can also be oxidized by arsenic pentafluoride to  $\text{Se}_4(\text{AsF}_6)_2$  (equation 4) and by antimony pentafluoride to  $\text{Se}_4(\text{Sb}_2\text{F}_{11})_2$  (equation 5) by heating the reactants in  $\text{SO}_2$  for several days<sup>31,38</sup> With a trace of halogen ( $\text{Cl}_2$ ,  $\text{Br}_2$ ,  $\text{I}_2$ ) or  $\text{AsCl}_4\text{AsF}_6$ , the reaction proceeds quantitatively in minutes.

Scheme 1

They also propose<sup>1</sup> a reaction pathway for the oxidation of  $\text{Se}_8^{2+}$  to  $\text{Se}_4^{2+}$  by  $\text{AsF}_5$  (Scheme 1).<sup>39</sup>

The  $\text{Se}_8^{2+}$  species may initially form a donor–acceptor adduct with  $\text{AsF}_5$  (2) by the donation of an electron pair from the axial fluorine in  $\text{AsF}_5$  to one of the positively charged three-coordinate selenium atoms. Another selenium atom of the ring donates an electron pair to the slightly positively charged arsenic atom, followed by rearrangement resulting in the formation of  $\text{Se}_8\text{F}_2^{2+}$  (3  $\rightarrow$  4). This species may rearrange to form (5). Finally, two  $\text{AsF}_5$  molecules abstract two  $\text{F}^-$  to form two molecules of  $\text{Se}_4^{2+}$  (5  $\rightarrow$  6).

Selenium reacts with an excess of  $\text{SbF}_5$  in  $\text{SO}_2$  at 363 K to form  $(\text{Se}_4)_2(\text{Sb}_4\text{F}_{17})(\text{SbF}_6)_3$ .<sup>40</sup> Two crystallographically independent  $\text{Se}_4^{2+}$  units with slight differences of Se–Se bond distances and angles (cation I, Se–Se 2.273, 2.276 Å, angles 90.5°, 89.5°; cation II, Se–Se 2.265, 2.276 Å, angles 90.7°, 89.3°) are found.<sup>36</sup>

None of these cations are stable in aqueous media or in any solvent containing small amounts of water, as they undergo disproportionation (equation 6).

They exist only in solvents with very low basicities, such as  $\text{H}_2\text{S}_2\text{O}_7$ ,  $\text{HSO}_3\text{F}$ ,  $\text{SO}_2$ , and  $\text{AsF}_5$ , and in the presence of anions such as  $\text{SO}_3\text{F}^-$ ,  $\text{HS}_2\text{O}_7^-$ ,  $\text{SbF}_6^-$ ,  $\text{Sb}_2\text{F}_{11}^-$ ,  $\text{AsF}_6^-$ , and  $\text{AlCl}_4^-$ , all of which are very weak bases of very strong corresponding acids.

### 2.1.2 $\text{Se}_8^{2+}$ Cation

Conductivity measurements on solutions of selenium in highly acidic and oxidizing solutions indicate the formation of  $\text{Se}_8^{2+}$ .<sup>10,12</sup> Solutions of  $\text{Se}_8^{2+}$  in 100%  $\text{H}_2\text{SO}_4$  are prepared by heating selenium in the acid at 50–60 °C (equation 7). Green solutions of  $\text{Se}_8^{2+}$  are also obtained by dissolving selenium in disulfuric acid (equation 8). The solutions are not stable, and further oxidation yields yellow solutions containing  $\text{Se}_4^{2+}$ . Salts of  $\text{Se}_8^{2+}$  are also obtained using  $\text{SbF}_5$  or  $\text{AsF}_5$  as oxidizing agents in an inert solvent such as  $\text{SO}_2$  or  $\text{HF}$  (equation 9).<sup>41,42</sup>

Both deep-green compounds undergo instant disproportionations in the presence of moist air (equation 6). Dissolution of  $\text{Se}_8(\text{AsF}_6)_2$  or  $\text{Se}_8(\text{Sb}_2\text{F}_{11})_2$  in 100% sulfuric acid, oleum, or fluorosulfuric acid, however, yields stable green solutions with typical absorption maxima at 295, 470, and 685 nm for the  $\text{Se}_8^{2+}$  cations.<sup>29</sup>

From phase diagram studies on the pseudobinary  $\text{Se}-(\text{SeCl}_4 + 4\text{AlCl}_3)$  system, the compounds  $\text{Se}_4(\text{AlCl}_4)_2$  and  $\text{Se}_8(\text{AlCl}_4)_2$  have been identified.<sup>43,44</sup>  $\text{Se}_8(\text{AlCl}_4)_2$  alone was prepared from a stoichiometric mixture of  $\text{Se}$ ,  $\text{SeCl}_4$ , and  $\text{AlCl}_3$

**Figure 1** Structure of the bicyclic cation  $\text{Se}_8^{2+}$

after fusion at 250 °C for 3 h to produce black prismatic crystals (equation 11).  $\text{Se}_8(\text{AlCl}_4)_2$  can also be prepared by the reaction of  $\text{Se}_2\text{Cl}_2$  with  $\text{AlCl}_3$  in  $\text{SO}_2$  (equation 12).<sup>45</sup> The structure of  $\text{Se}_8(\text{AlCl}_4)_2$  shows an endo–exo conformation of the eight-membered ring with approximate  $C_s$  symmetry (Figure 1).

The bond lengths around the ring vary between 2.29 and 2.36 Å and do not differ significantly from those found in  $\alpha$  and  $\beta$  selenium. The most striking difference between the  $\text{Se}_8^{2+}$  ion and the cyclic  $\text{Se}_8$  molecules is the transannular bond, whose length of 2.84 Å is significantly shorter than the van der Waals contact separation of 4.0 Å.

The bond compensates for the removal of two electrons from  $\text{Se}_8$  and is accompanied by the folding up of one end of the eight-membered ring. By removing two more electrons, the unknown  $\text{Se}_8^{4+}$  cation would result (decomposes to  $\text{Se}_4^{2+}$ ). Interestingly, the structure of the isoelectronic  $\text{Se}_4\text{N}_4$  molecule shows exactly the structure predicted for the hypothetical  $\text{Se}_8^{4+}$ , with the other end of the ring folding up and with a second transannular  $\text{Se} \cdots \text{Se}$  bond. Thus,  $\text{Se}_8^{2+}$  appears to be the midpoint between the cage molecule of  $\text{Se}_4\text{N}_4$  and the crown-shaped ring of  $\text{Se}_8$  (Figure 2).<sup>46</sup>

### 2.1.3 $\text{Se}_{10}^{2+}$ Cation

The hexafluoroarsenate and hexafluoroantimonate salts  $\text{Se}_{10}(\text{AsF}_6)_2$  and  $\text{Se}_{10}(\text{SbF}_6)_2$ , containing the polyatomic

**Figure 2** Gradual oxidation of  $\text{Se}_8$  to ' $\text{Se}_8^{4+}$ '

**Figure 3** View of the  $\text{Se}_{10}^{2+}$  cation in  $\text{Se}_{10}(\text{SbF}_6)_2$

cation  $\text{Se}_{10}^{2+}$ , were prepared by the reaction of excess selenium with  $\text{AsF}_5$  or  $\text{SbF}_5$  in  $\text{SO}_2$  (equation 13) or the reaction of  $\text{Se}_8(\text{AsF}_6)_2$  with elemental selenium in  $\text{SO}_2$  (equation 14).  $\text{Se}_{10}(\text{SbF}_6)_2$  can also be prepared similarly by disproportionation of  $\text{Se}_8(\text{AlCl}_4)_2$  on washing with large quantities of  $\text{SO}_2$  (equation 15).

The structure of  $\text{Se}_{10}(\text{SbF}_6)_2$  shows the cation to be of the bicyclo[4.2.2]decane type with approximate  $C_2$  symmetry (Figure 3).<sup>45</sup> It consists of a six-membered, boat-shaped ring bridged by a chain of four selenium atoms to form an eight-membered ring. The six bonds to the three-coordinate atoms are the longest (2.41–2.44 Å). The adjacent bonds (2.24–2.26 Å) and the unique central bond in the bridging chain (2.35 Å) are shorter. The four short bonds are comparable to those in  $\text{Se}_4^{2+}$  salts, for example, in  $\text{Se}_4(\text{HS}_2\text{O}_7)$  (2.28 Å) which have bond orders of 1.25 according to simple valence bond considerations. Spectrophotometric and potentiometric studies of cationic species of selenium in  $\text{NaCl-AlCl}_3$  melts have been interpreted as indicating the presence of  $\text{Se}_{12}^{2+}$  and  $\text{Se}_{16}^{2+}$ ,<sup>1,47</sup> but the structures of these cations are unknown.

## 2.2 Derivatives of Selenium Rings

### 2.2.1 $\text{Se}_4\text{I}_4^{2+}$ Cation

The  $\text{Se}_4\text{I}_4^{2+}$  cation is formed by the reaction of  $\text{Se}_4(\text{AsF}_6)_2$  and  $\text{I}_2$  in a 1:2 ratio.

Such solutions were studied by  $^{77}\text{Se}$  NMR.<sup>41</sup> The coupling patterns are consistent with a four-membered ring or chain species. Ab initio energy calculations indicate a chain structure (7).

### 2.2.2 $\text{Se}_6\text{I}_2^{2+}$ and $(\text{Se}_6\text{I}^+)_n$ Cations

The salts  $\text{Se}_6\text{I}_2(\text{AsF}_6)_2 \cdot 2\text{SO}_2$ <sup>48,49</sup> and  $(\text{Se}_6\text{I})_n \cdot n\text{AsF}_6$ ,<sup>49,50</sup> containing stable selenium–iodine cations, have been prepared and characterized by X-ray crystallography. Both  $\text{Se}_6\text{I}_2^{2+}$  and  $(\text{Se}_6\text{I}^+)_n$  are derivatives of the chair form of selenium.<sup>1</sup>  $(\text{Se}_6\text{I})_n \cdot n\text{AsF}_6$  is obtained quantitatively by reacting stoichiometric amounts of Se,  $\text{I}_2$ , and  $\text{AsF}_5$  in  $\text{SO}_2$  (equation 17).  $\text{Se}_6\text{I}_2(\text{AsF}_6)_2 \cdot 2\text{SO}_2$  was prepared from  $\text{SO}_2$  solutions (equation 18).

The centrosymmetric  $\text{Se}_6\text{I}_2^{2+}$  cation (Figure 4) contains hexaselenium rings with a chair conformation similar to  $\text{Se}_6$ .<sup>48</sup> The  $\text{Se}_6$  ring is substituted in the 1,4-positions by two iodine atoms in an endo conformation. The tricoordinate selenium atoms in the  $\text{Se}_6\text{I}_2^{2+}$  cation are positively charged. A Se–Se bond alternation between tri- and dicoordinate selenium atoms is observed, similar to other related rings and to the hexaselenium ring of  $\text{Se}_{10}^{2+}$ . The Se–I bonds (2.468 Å) are shorter than in  $\text{SeI}_3^+$  (2.510 Å), implying  $4p_\pi-4p_\pi$  and  $4p_\pi-5p_\pi$  bonding. There are four intracationic I–Se contacts (average 3.714 Å; van der Waals radii 4.15 Å), leading to a distorted cube-like shape of the cation. This interaction must be attractive, otherwise the less sterically hindered *exo* conformation would be preferred.

The  $(\text{Se}_6\text{I}^+)_n$  cation in  $(\text{Se}_6\text{I})_n \cdot n\text{AsF}_6$  has a two-dimensional polymeric structure. The geometry of the  $\text{Se}_6\text{I}_2$

**Figure 4** Structure of  $\text{Se}_6\text{I}_2^{2+}$

**Figure 5** The polymeric  $(\text{Se}_6\text{I}^+)_n$  cation

unit is similar to that in  $\text{Se}_6\text{I}_2^{2+}$  (see above), with the iodine atoms bridging the  $\text{Se}_6$  rings (Figure 5).<sup>49</sup> The bond alternation within the  $\text{Se}_6$  ring is less pronounced than that in  $\text{Se}_6\text{I}_2^{2+}$ , consistent with the lower charge per ring.

### 2.2.3 $\text{Ph}_2\text{Se}_6^{2+}$ Cation

$\text{Se}_4(\text{AsF}_6)_2$  reacts with  $\text{Ph}_2\text{Se}_2$  in liquid  $\text{SO}_2$  at room temperature to give bright orange crystals of  $\text{Ph}_2\text{Se}_6(\text{AsF}_6)_2 \cdot \text{SO}_2$ .<sup>42</sup> This compound contains a six-membered selenium ring in a boat conformation with two phenyl groups in the 1,4-positions (Figure 6). The six-membered selenium rings  $\text{Se}_6$ ,  $\text{Se}_6\text{I}^+$ , and  $\text{Se}_6\text{I}_2^{2+}$  (see above) are all in the chair form. A reaction pathway was proposed (Scheme 2) with an initial trigonal prismatic intermediate

**Figure 6**  $\text{Ph}_2\text{Se}_6^{2+}$  cation in  $\text{Ph}_2\text{Se}_6(\text{AsF}_6)_2 \cdot \text{SO}_2$

or transition state, which rearranges to form the final boat conformation.<sup>42</sup>

**Scheme 2**

Figure 7  $\text{Se}_9\text{Cl}^+$  cation in  $\text{Se}_9\text{Cl}(\text{SbCl}_6)$

#### 2.2.4 $\text{Se}_9\text{Cl}^+$ Cation

The compound  $\text{Se}_9\text{Cl}(\text{SbCl}_6)$  is prepared by the reaction of selenium with  $\text{NO}\text{SbCl}_6$  in  $\text{SO}_2$ .<sup>51</sup> It is the first example of a seven-membered selenium ring (Figure 7). A  $\text{Se}_2\text{Cl}$  chain is joined to the ring which is in the chair conformation and in which the alternating Se–Se bond lengths around the ring vary from 2.270 to 2.430 Å.<sup>52</sup>

### 2.3 Acyclic Cationic Systems

$\text{Se}_2\text{Br}_5^+$ , as the first reported example of a novel dinuclear cationic halogen–chalcogen species, was prepared as the deep-purple crystalline hexafluoroarsenate.<sup>52</sup> The cation consists of two trigonal pyramidal  $\text{SeBr}_3$  units connected via a linear Se–Br–Se bridge. The formally positive  $\text{Br}^+$  links two  $\text{SeBr}_2$  molecules with formal oxidation number +2 for Se.

Reaction of selenium, bromine, and arsenic pentafluoride in liquid  $\text{SO}_2$  leads to crystalline  $(\text{Se}_3\text{Br}_3)(\text{AsF}_6)$ . The crystal structure consists of discrete  $\text{Br}_2\text{Se}^+\text{SeSeBr}$  and  $\text{AsF}_6^-$  ions. The Se–Se bond lengths are 2.554 Å and 2.211 Å. The selenium–selenium bond alternation of 0.34 Å implies the presence of substantial partial  $4p_\pi$ – $4p_\pi$  bonding between the Se atoms in the Se–Se–Br unit.<sup>53</sup>

$\text{Se}_2\text{I}_4^{2+}$  has been reported recently as the first example of a novel type of diselenium tetraiodine(2+) cation.<sup>54</sup> It was synthesized by reaction of selenium with  $[\text{I}_2][\text{Sb}_2\text{F}_{11}]$  in liquid  $\text{SO}_2$ . The cation consists of two  $\text{SeI}_2^+$  units connected by a very weak Se–Se bond (2.841 Å) and has an eclipsed structure. The Se–Se bond length is comparable to the transannular bond in  $\text{Se}_8^{2+}$ .

### 2.4 Heterocyclic Selenium Cations

#### 2.4.1 $\text{S}_3\text{Se}^{2+}$ Cation

The heterochalcogen cations  $\text{S}_x\text{Se}_{4-x}^{2+}$  ( $x = 0$ –3) have been characterized in  $\text{SO}_2$  solution by  $^{77}\text{Se}$  NMR studies. X-ray structural analysis of  $(\text{S}_{3.0}\text{Se}_{1.0})_2(\text{Sb}_4\text{F}_{17})(\text{SbF}_6)_3$ <sup>55</sup> have shown that the compound consists of two crystallographically independent  $\text{S}_{3.0}\text{Se}_{1.0}^{2+}$  cations (for mixed Se/Te heterocyclic cations see *Tellurium: Inorganic Chemistry*).

## 3 HALIDES AND RELATED COMPOUNDS

### 3.1 Monohalides

#### 3.1.1 $\text{SeF}$ , $\text{SeCl}$ , and $\text{SeBr}$ Radicals

Until recently, no selenium monohalide could be isolated; only the short-lived radicals  $\text{SeF}$ ,  $\text{SeCl}$ , and  $\text{SeBr}$  were identified in the gas phase.  $\text{SeF}$ , can be produced by reaction of fluorine atoms (by passing  $\text{CF}_4$  through a microwave discharge) with carbonyl selenide in a flow system. It has been detected by ESR spectroscopy<sup>56,57</sup> and the Se–F bond length (1.742 Å) is close to the value reported for  $\text{SeF}_2$  (1.69 Å), deduced from infrared spectra.<sup>9,58</sup>

$\text{SeCl}$  is formed by flash photolysis of  $\text{SeCl}_2$  in the presence of  $\text{N}_2$  or Ar. Addition of oxygen results in the formation of  $\text{SeO}$ .<sup>59</sup> Formation of  $\text{SeCl}$  is assumed when liquid selenium is in equilibrium with gaseous  $\text{SeCl}_2$  at 280 °C (equation 20).<sup>60</sup> Gaseous  $\text{SeBr}$  was observed by its UV spectrum during the flash photolysis of  $\text{Se}_2\text{Br}_2$  vapor at 50–55 °C in a mixture with nitrogen (75 mbar).<sup>61</sup> Both  $\text{SeCl}_2$  and  $\text{SeBr}_2$  are available as solutions in thf.<sup>62</sup>

#### 3.1.2 $\text{Se}_2\text{F}_2$ , $\text{Se}_2\text{Cl}_2$ , $\text{Se}_2\text{Br}_2$ , and $\text{Se}_2\text{I}_2$

A mixture of lower selenium fluorides is obtained by the reaction between heated selenium (210 °C) and fluorine, highly diluted with argon.  $\text{FSeSeF}$  and the other species are detected by IR spectroscopy. UV irradiation of matrix-isolated  $\text{FSeSeF}$  yields thermodynamically less stable  $\text{Se}=\text{SeF}_2$ .<sup>63</sup>

Selenium reacts with a stoichiometric amount of  $\text{SeCl}_4$  to form reddish-brown liquid  $\text{Se}_2\text{Cl}_2$ .  $\text{Se}_2\text{Br}_2$  can easily be prepared from the elements. Both have been characterized by X-ray structure analyses.<sup>64</sup> There are two different structure types ( $\text{Se}_2\text{Cl}_2$ ,  $\beta$ - $\text{Se}_2\text{Br}_2$ , and  $\alpha$ - $\text{Se}_2\text{Br}_2$ ) containing X–Se–Se–X molecules with approximate  $C_2$  symmetry and with dihedral angles of 87.4° ( $\text{Se}_2\text{Cl}_2$ ) and 86.4° ( $\text{Se}_2\text{Br}_2$ ). The average Se–X bond lengths are 2.202 Å (Se–Cl) and 2.364 Å (Se–Br). Different degrees of association of the molecules through  $\text{Se} \cdots \text{Se}$  and  $\text{Se} \cdots \text{X}$  contacts connect the molecules to layers and three-dimensional nets.

Orthorhombic  $\alpha$ - $\text{Se}_2\text{Br}_2$  is thermodynamically stable compared to the monoclinic  $\beta$ - $\text{Se}_2\text{Br}_2$  modification. Monotropic exothermic transformation of the metastable into the stable form occurs in the range –40 to –5 °C.

In the gas phase,  $\text{Se}_2\text{Cl}_2$  and  $\text{Se}_2\text{Br}_2$  are not detectable because of dissociation into selenium and gaseous  $\text{SeX}_2$ .  $\text{Se}_2\text{Cl}_2$  is able to form ionic complexes with strong Lewis acids.<sup>65</sup> Reaction of  $\text{Se}_2\text{Cl}_2$  with  $\text{BCl}_3$  and  $\text{SbCl}_5$  in liquid sulfur dioxide at –40 °C forms  $\text{Se}_2\text{Cl}_2 \cdot \text{BCl}_3$  and  $\text{Se}_2\text{Cl}_2 \cdot \text{SbCl}_5$ . Their IR spectra suggest ionic structures  $[\text{Se}_2\text{Cl}]^+[\text{BCl}_4]^-$

and  $[\text{Se}_2\text{Cl}]^+[\text{SbCl}_6]^-$ . At room temperature, both compounds disproportionate to yield selenium and  $\text{SeCl}_4 \cdot \text{BCl}_3$  or  $\text{SeCl}_4 \cdot \text{SbCl}_5$ .

An interesting reaction occurs between  $\text{Se}_2\text{Cl}_2$  and  $\text{S}_4\text{N}_4$  in the presence of thionyl chloride:<sup>66</sup> Thiatrithiazyl chloride,  $\text{S}_4\text{N}_3\text{Cl}$ , is formed, together with a compound of empirical formula  $\text{SeS}_2\text{N}_2\text{Cl}_2$ . From IR spectroscopy a structure corresponding to that of selenotrithiazyl hexachloroselenate(IV),  $(\text{SeS}_3\text{N}_3)_2\text{SeCl}_6$ , has been suggested. The cation in this salt may have the configurations (8) or (9).

Simple binary selenium iodides are generally regarded as being nonexistent,<sup>61</sup> although several stable species with Se–I bonds have been reported:  $\text{SeO}_2\text{I}^-$ ,<sup>67</sup>  $\text{SeOClI}$ ,<sup>68</sup> areneselenium iodides,<sup>69</sup>  $\text{SeI}_6^{2-}$ ,<sup>70</sup>  $\text{SeI}_3^+$ ,<sup>71</sup>  $(\text{C}_2\text{F}_5)\text{SeI}_2^+$ ,<sup>71</sup>  $\text{Se}_2\text{I}_4^{2+}$ ,<sup>54</sup>  $\text{Se}_4\text{I}_4^{2+}$ ,<sup>41</sup>  $\text{Se}_6\text{I}_2^{2+}$ ,<sup>48,49</sup> and  $(\text{Se}_6\text{I})_n^{n+}$ .<sup>50,51</sup> <sup>77</sup>Se NMR studies of solutions of selenium with iodine in carbon disulfide have been recently reviewed. These spectra indicate the presence of the selenium iodides  $\text{Se}_3\text{I}_2$ ,  $\text{Se}_2\text{I}_2$ , and  $\text{SeI}_2$  in such solutions, with  $\text{Se}_2\text{I}_2$  as the main product.

### 3.2 Dihalides

Among the selenium dihalides,  $\text{SeF}_2$ ,  $\text{SeCl}_2$ , and  $\text{SeBr}_2$  are known to exist in the gas phase, while  $\text{SeCl}_2$ <sup>62</sup> and  $\text{SeBr}_2$  are also known in solution.  $\text{SeF}_2$  is obtained together with  $\text{FSeSeF}$  and  $\text{SeF}_4$  by the reaction of heated selenium vapor with elemental fluorine diluted with argon (see above).<sup>63</sup>  $\text{SeF}_2$  was also synthesized in good yield by UV photolysis of  $\text{CF}_3\text{SeF}_3$  and isolated in an argon matrix:<sup>72</sup>

IR spectra suggest the structure of the  $\text{SeF}_2$  molecule to be nonlinear.<sup>63</sup> Photolysis of  $\text{SeCl}_2$  as well as of  $\text{SeBr}_2$  in an electrical discharge yields  $\text{SeX} \cdot$  radicals.<sup>59</sup> In the case of the diselenium dihalides, only  $\text{Se}_2\text{Br}_2$  gives detectable amounts of  $\text{SeBr} \cdot$  species.<sup>73</sup>

Vapor pressure experiments and vibrational spectroscopic studies<sup>74–77</sup> show that  $\text{SeCl}_2$  and  $\text{SeBr}_2$  exist as dissociation products of the corresponding tetrahalides in the vapor phase or in organic solvents,<sup>78</sup> or as mixtures of  $\text{SeO}_2$  and Se in aqueous  $\text{HCl}$ .<sup>79</sup> Their nonlinear structures were determined by photoelectron spectra and by electron diffraction.<sup>80–82</sup>

A remarkable stabilization of selenium dihalides is achieved if the central  $\text{Se}^{\text{II}}$  atom is coordinated with anionic (see Section 4.2) or neutral Lewis bases as ligands.

$\text{SeBr}_2$  as well as  $\text{SeCl}_2$  can be stabilized as crystalline tetramethylthiourea (tmtu) adducts,  $\text{SeX}_2(\text{tmtu})$  ( $\text{X} = \text{Cl}, \text{Br}$ ) (equations 22–23).<sup>62,83</sup>

$\text{SeBr}_2(\text{tmtu})$ <sup>83</sup> has a T-shaped heavy-atom  $\text{SSeBr}_2$  framework (10), as previously suggested by IR spectroscopic studies.<sup>84</sup> The  $\text{SeBr}_2(\text{tmtu})$  molecule can be described as a dimer with  $\text{Se} \cdots \text{Br}$  contacts (3.34 Å) trans to sulfur that are shorter than the sum of the van der Waals radii (3.95 Å).<sup>83</sup> The arrangement around Se is distorted square planar.

When triarylphosphane ligands are introduced as two-electron donors by the reaction of triarylphosphane selenide with  $\text{Br}_2$ , the product is T-shaped  $\text{Ar}_3\text{PSeBr}_2$  with the Br ligands in the trans position.<sup>85</sup>

### 3.3 Tetrahalides

#### 3.3.1 Selenium Tetrafluoride

Selenium tetrafluoride can be prepared in various reactions involving a fluorinating agent ( $\text{AgF}$ ,  $\text{ClF}$ ,  $\text{ClF}_3$ ,  $\text{CoF}_3$ ,  $\text{SF}_4$ ,  $\text{F}_2$ ,  $\text{BrF}_3$ ) acting upon elemental selenium,  $\text{SeO}_2$ ,  $\text{SeCl}_2$ , or  $\text{SeCl}_4$ . Another convenient method of preparation<sup>86</sup> uses  $\text{SeF}_4$  itself as the reaction medium during the fluorination (equation 24).

$\text{SeF}_4$  is a useful fluorinating agent, especially in organic chemistry, as it has some advantages over  $\text{SF}_4$ . It permits milder conditions and, because of its convenient liquid temperature range, it can be employed at atmospheric pressure.<sup>86</sup> Dissolved  $\text{SeF}_4$  molecules have a  $\psi$ -trigonal bipyramidal structure like  $\text{SF}_4$ . If the enhanced concentration is increased, gradual intermolecular association of the molecules is observed.<sup>87</sup>

An X-ray structure determination of  $\text{SeF}_4$ <sup>88</sup> essentially confirmed the results of detailed vibrational spectroscopic investigations.<sup>89–91</sup> There is significant intermolecular association of the  $\psi$ -trigonal bipyramidal  $\text{SeF}_4$  molecules in the solid state; however, it is much weaker than in  $\text{TeF}_4$  where

**Figure 8** Polymeric structure of  $\text{TeF}_4$  and the arrangement of monomeric  $\text{SeF}_4$  subunits

**Figure 9** Coordination of selenium in crystalline  $\text{SeF}_4$  as compared to the Te coordination in crystals of polymeric  $\text{TeF}_4$

polymeric chains with square-pyramidal coordination of Te are formed (Figures 8 and 9).<sup>92</sup>

$^{19}\text{F}$  NMR investigations have detected rapid intermolecular fluorine exchange in liquid  $\text{SeF}_4$ .<sup>93</sup> From conductometric measurements,  $\text{SeF}_4$  in liquid hydrogen fluoride solution has been shown to be a weak base (equation 25).<sup>94</sup>

The estimated value of the ionization constant ( $K_b = 4 \times 10^{-4}$ ) indicates that  $\text{SeF}_4$  is a weaker base in HF than  $\text{SF}_4$  ( $K_b = 4 \times 10^{-2}$ ).<sup>95</sup> The adducts of selenium tetrafluoride with Lewis acids are considered to be ionic compounds containing the  $\text{SeF}_3^+$  cation. The systems of  $\text{SeF}_4$  with  $\text{BF}_3$ ,  $\text{SbF}_5$ ,  $\text{AsF}_5$ ,  $\text{NbF}_5$ , and  $\text{TaF}_5$  have been studied.<sup>94,96,97</sup> Crystal structure determinations of  $\text{SeF}_4 \cdot \text{NbF}_5$  and  $\text{SeF}_4 \cdot 2\text{NbF}_5$  show that they are composed of the  $\text{SeF}_3^+$  and  $\text{NbF}_6^-$  or  $\text{Nb}_2\text{F}_{11}^-$  ions, respectively, although there is considerable interaction between the ions through fluorine bridging.<sup>98,99</sup> In the case of  $\text{SeF}_3 \cdot \text{NbF}_6$ , four formula units are linked to give Se and Nb atoms at alternate corners of a distorted cube, while for  $\text{SeF}_3 \cdot \text{Nb}_2\text{F}_{11}$  the ions interact to form endless chains.

Conductometry and  $^{19}\text{F}$  NMR spectroscopy have been used to study the systems of  $\text{SeF}_4$  with  $\text{BF}_3$  in HF.<sup>94</sup> Fluorine-bridged structures such as in  $\text{SeF}_4 \cdot \text{NbF}_5$  and  $\text{SeF}_4 \cdot 2\text{NbF}_5$  with polymeric molecules and ions are present. The simplest equilibrium of this type involves the dimer  $(\text{SeF}_4 \cdot \text{BF}_3)_2$ , which may be either linear or cyclic.<sup>94</sup>

IR, Raman, and NMR studies of an adduct of  $\text{SeF}_4$  with  $\text{SO}_2$  in the solid and molten states are best interpreted as indicating a polymeric fluorosulfate-bridged structure.<sup>100</sup>

Adducts formed between  $\text{SeF}_4$  and alkali metal fluorides<sup>101</sup> have been characterized by vibrational spectroscopy.<sup>102</sup> The observed Raman and IR spectra of  $\text{CsSeF}_5$  indicate an ionic structure involving a square-pyramidal anion of  $C_{4v}$  symmetry.

### 3.3.2 Selenium Tetrachloride and Selenium Tetrabromide

Two characteristic structural and bonding features of the chlorine and bromine compounds of selenium(IV), in which the role of the inert pair determines much of stereochemistry and reactive properties of the entire class of compounds, are already evident in the simple binary halides.

1. Selenium(IV) as well as sulfur(IV) and tellurium(IV) tend to form a more or less distorted quasioctahedral (hypervalent)  $\text{XY}_{3+3}\text{E}$  or  $\text{XY}_{4+2}\text{E}$  coordination of six nearest neighbors in which there is a tendency to form stable trigonal pyramidal  $\text{XY}_3^+$  subunits ( $\text{X} = \text{Se}, \text{Y} = \text{Cl}, \text{Br}, \text{I}; \text{E}$  is a more or less stereochemically active electron pair).
2. The harder (in Pearson's model<sup>103</sup>) or the more electronegative the ligand, the more pronounced the stereochemical activity of the inert electron pair localized at the chalcogen atom.

**Selenium Tetrachloride.** Selenium tetrachloride is usually prepared from the elements and decomposes thermally (equation 27).<sup>104,105</sup>

As recent thermoanalytical and X-ray diffraction investigations show,  $\text{SeCl}_4$  can be prepared in two polymorphic modifications, a metastable  $\beta$ -form<sup>8,106,107</sup> and a thermodynamically stable  $\alpha$ -modification.<sup>108,109</sup> Crystallization from solvents such as  $\text{POCl}_3$ , sublimation of gaseous  $\text{SeCl}_4$  into a zone with  $T < 150^\circ\text{C}$ , or crystallization from the melt ( $360^\circ\text{C}$ ) yields  $\beta$ - $\text{SeCl}_4$ .

Increasing the sublimation and desublimation temperature ( $T_d \sim 200^\circ\text{C}$ ) causes the transformation of initial primary product,  $\beta$ - $\text{SeCl}_4$  into  $\alpha$ - $\text{SeCl}_4$ . Thus crystallization from the gas phase obeys Ostwald's rule.<sup>106,110</sup>  $\alpha$ - $\text{SeCl}_4$  is also formed

in the solid state by monotropic transformation above 180 °C. Stable selenium tetrachloride ( $\alpha$ -SeCl<sub>4</sub>)<sup>109</sup> contains Se<sub>4</sub>Cl<sub>16</sub> molecules.

$\beta$ -SeCl<sub>4</sub> is isostructural with TeCl<sub>4</sub> and also contains tetrameric cubane-like Se<sub>4</sub>Cl<sub>16</sub> molecules with approximate  $T_d$  symmetry. Within the distorted SeCl<sub>3+3</sub> octahedra, the bonds to the triply bridging chlorine ligands are much longer than to the terminal chlorines. The bonding can be described either as covalent Se<sub>4</sub>Cl<sub>16</sub> molecules, or, in an ionic approximation, as [(SeCl<sub>3</sub><sup>+</sup>Cl<sup>-</sup>)<sub>4</sub>] with a certain degree of stereochemical activity of the lone pairs toward the center of the voluminous cubane center (Figure 10).<sup>111,112</sup> In the presence of strong Lewis acids, the SeCl<sub>4</sub> molecule ionizes and [SeCl<sub>3</sub>]<sup>+</sup> ions are formed by chloride ion transfer (equation 28).<sup>113</sup>

The [SeCl<sub>3</sub>]<sup>+</sup> ion is also formed in chlorosulfuric acid containing Se<sub>2</sub>Cl<sub>2</sub><sup>114</sup> or selenium and chlorine.<sup>115</sup>

Solid compounds containing [SeCl<sub>3</sub>]<sup>+</sup> cations have been well characterized. Thus in the case of the SeCl<sub>4</sub>·AlCl<sub>3</sub> adduct, the presence of discrete [SeCl<sub>3</sub>]<sup>+</sup> and [AlCl<sub>4</sub>]<sup>-</sup> ions has been shown by an X-ray structure determination.<sup>116</sup> The structure contains distorted SeCl<sub>6</sub> octahedra with three long and three short Se–Cl bonds of 3.04 and 2.11 Å (mean values). The spectra have been interpreted by assuming pyramidal [SeCl<sub>3</sub>]<sup>+</sup> ions with  $C_{3v}$  symmetry.<sup>117–121</sup>

Selenium tetrachloride behaves as an ansolvo acid in an SbCl<sub>3</sub> melt (equation 29).

Figure 10 Se<sub>4</sub>Cl<sub>16</sub> molecule in the structure of  $\beta$ -SeCl<sub>4</sub>

Strong association of the ions was found by cryoscopy.<sup>122</sup> In the SeCl<sub>4</sub>–SbCl<sub>5</sub> system, a compound of the composition SeCl<sub>4</sub>·SbCl<sub>5</sub> was concluded from the phase diagram.<sup>123</sup> SeCl<sub>4</sub> and excess SbCl<sub>5</sub> heated to 140–150 °C yield SeCl<sub>4</sub>·SbCl<sub>5</sub><sup>97</sup> (SeCl<sub>3</sub><sup>+</sup>SbCl<sub>6</sub><sup>-</sup>),<sup>117</sup> which is also obtained by reaction in SOCl<sub>2</sub> solution.<sup>124</sup>

Unlike SeF<sub>4</sub>, which forms 1:1 ionic complexes containing the SeF<sub>5</sub><sup>-</sup> ion with alkali metal fluorides,<sup>101,102</sup> only octahedral ions of the type [SeX<sub>6</sub>]<sup>2-</sup> are known for SeCl<sub>4</sub> and SeBr<sub>4</sub> (equation 30).

Some remarkable N-substituted derivatives of SeCl<sub>4</sub> with significant Se–N multiple bonding were reported from the reaction of Ph<sub>3</sub>P–N–SiMe<sub>3</sub> with SeCl<sub>4</sub>. The first product isolated was Ph<sub>3</sub>P–N–SeCl<sub>3</sub>, in which another chlorine can be replaced to give (Ph<sub>3</sub>P=N)<sub>2</sub>SeCl<sub>2</sub>. On addition of SbCl<sub>5</sub> at –78 °C, one Cl is abstracted and [(Ph<sub>3</sub>P=N)<sub>2</sub>SeCl<sup>+</sup>][SbCl<sub>6</sub><sup>-</sup>] is formed.<sup>125</sup> Cl<sub>2</sub>Se=NTeF<sub>5</sub>, obtained as a reaction product from SeCl<sub>4</sub> and H<sub>2</sub>NTeF<sub>5</sub>,<sup>126</sup> is postulated to contain a Se=N double bond.

**Selenium Tetrabromide.** Selenium tetrabromide is mainly prepared by the reaction of the elements, either pure or dissolved in CS<sub>2</sub>, using an excess of bromine. It occurs in two crystalline modifications, the thermodynamically stable  $\alpha$ -SeBr<sub>4</sub> and the metastable  $\beta$ -SeBr<sub>4</sub>. The latter forms first, in accordance with Ostwald's rule.

$\alpha$ -SeBr<sub>4</sub> crystallizes in the trigonal system and contains cubane-like [SeBr<sub>4</sub>]<sub>4</sub> units.<sup>106</sup> Monoclinic  $\beta$ -SeBr<sub>4</sub> also consists of tetrameric cubane-like [SeBr<sub>4</sub>]<sub>4</sub> molecules.  $\beta$ -SeBr<sub>4</sub> is isotypic with TeCl<sub>4</sub><sup>127</sup> and with  $\beta$ -SeCl<sub>4</sub>; its chemical behavior and reactions are similar to SeCl<sub>4</sub>.

### 3.3.3 Reactions of the Tetrahalides

Owing to their remarkable structural and bonding properties, their high general reactivity, and the significant influence of the lone pair on the reaction path and products, the reactions of the selenium(IV) halides are quite variable.

- + selenium (IV)oxide  $\longrightarrow$  selenium (IV)oxide halide
- + selenium (IV)oxide +  $\text{R}^+\text{Y}^- \longrightarrow$  oxohaloselenates(IV)
- + reducing agents +  $\text{R}^+\text{Y}^- \longrightarrow$  haloselenates(II)
- + alkyl(aryl)ating agents  $\longrightarrow$  organoselenium(IV)halides
- + halides BY<sub>n</sub> as Lewis acids / bases  $\longrightarrow$  'ionic' adducts
- + aqueous conc. HY  $\longrightarrow$  hydronium haloselenates(IV)
- + superacids  $\longrightarrow$  haloselenium polycations

Scheme 3

A wide variety of derivatives have been prepared according to the following reaction types (where Y = halogen, R<sup>+</sup> = metal ions or large cations such as tetraphenylphosphonium (arsonium)) (Scheme 3).

### 3.4 Hexahalides

#### 3.4.1 Selenium Hexafluoride

SeF<sub>6</sub> can be prepared, stepwise directly from the elements (equation 31).<sup>128</sup> A patent claims the formation of selenium hexafluoride from selenium and chlorine monofluoride, ClF, at temperatures above 200 °C under substantially anhydrous conditions. Below 200 °C, SeF<sub>4</sub> is formed.<sup>129</sup> The rotational movements of the SeF<sub>6</sub> molecules in the plastic and liquid phases have been studied by <sup>19</sup>F NMR, IR, and Raman spectroscopy.<sup>130</sup>

X-ray measurements were made on polycrystalline material. It does not seem to be isotopic with the orthorhombic UF<sub>6</sub>, as found by neutron diffraction.<sup>131</sup> SeF<sub>6</sub> is relatively inert to hydrolysis. It does not interact with water at room temperature over long periods, not even at elevated temperature.<sup>132</sup> The gas can be passed without change through aqueous 10% NaOH solution<sup>133</sup> and is resistant to aqueous 10% KOH solution as well.

#### 3.4.2 Selenium Pentafluoride Chloride

Selenium pentafluoride chloride is the first compound isolated containing a stable Se–Cl bond. It was first obtained from SeF<sub>4</sub> and ClF,<sup>134</sup> but is best prepared from CsSeF<sub>5</sub> and ClOSO<sub>2</sub>F.<sup>135</sup>

Normal-coordinate analyses were carried out for SeF<sub>5</sub>Cl.<sup>136–138</sup> There is a decrease of the stretching force constant values from SeF<sub>6</sub> to SeF<sub>5</sub>Cl, demonstrating that the substitution of one fluorine atom in SeF<sub>6</sub> by the less electronegative chlorine atom causes an increased polarity of the remaining Se–F bonds.

## 4 OXIDES

### 4.1 Properties of the Se–O Bond

The bond parameters of the oxygen compounds of selenium compared to those of sulfur have been investigated.<sup>139</sup> The

basic similarity between the bonding in these compounds, related to the model of a p<sub>π</sub>–d<sub>π</sub> bond system, has been confirmed by means of a linear relationship between the SeO and SO valence force constants.<sup>140</sup> A similar linear relationship has also been found between the valence force constants and the length of the SeO bond.<sup>141</sup> The influence of electronegative substituents on the frequencies of XO bonds in IR spectra has been verified for compounds of the type A–SeO–B.<sup>142</sup>

### 4.2 Selenium Dioxide

In the solid state, SeO<sub>2</sub> has a polymeric structure of corner-linked flattened SeO<sub>3</sub> pyramids, each carrying a pendant terminal O atom.<sup>143</sup> Mass spectrometric studies of the vapor over solid SeO<sub>2</sub> at 400 K indicate small amounts (1%) of dimeric SeO<sub>2</sub> in the gaseous phase.<sup>144</sup> A normal-coordinate calculation for the four possible symmetries of (SeO<sub>2</sub>)<sub>2</sub> prove the centrosymmetric C<sub>2h</sub> chair configuration (11) for the dimeric molecule.<sup>145</sup>

Selenium dioxide dissolves in H<sub>2</sub>S<sub>2</sub>O<sub>7</sub><sup>146</sup> to yield a colorless solution. From conductometry and cryoscopy measurements, it has been shown that, at low concentrations, SeO<sub>2</sub> may be protonated in H<sub>2</sub>S<sub>2</sub>O<sub>7</sub><sup>124</sup> in a similar manner as for H<sub>2</sub>SO<sub>4</sub> solutions (equation 34).<sup>147</sup>

The complex H<sub>2</sub>S<sub>2</sub>O<sub>7</sub>·Se<sub>2</sub>O<sub>4</sub> is proposed in concentrated solutions.<sup>146</sup> SeO<sub>2</sub> is also very soluble in water producing selenous acid (H<sub>2</sub>SeO<sub>3</sub>), from which it can be recovered by dehydration. It is readily reduced to the element by NH<sub>3</sub>, N<sub>2</sub>H<sub>4</sub>, or aqueous SO<sub>2</sub>. Thus it also finds use as an oxidizing agent in organic chemistry.

### 4.3 Selenium Trioxide

The structure of the trioxide consists of tetrameric cyclic molecules (SeO<sub>3</sub>)<sub>4</sub> of S<sub>4</sub> symmetry.<sup>148</sup> The mean Se–O distances are 1.55 Å for nonbridging oxygen and 1.77 Å for bridging oxygen. Electron diffraction<sup>149</sup> and mass spectrometry<sup>144</sup> of the vapor indicates that there is appreciable dissociation to the monomer at 120 °C. The Se–O distances in the monomeric SeO<sub>3</sub> molecule are 1.69 Å. In the molten state, selenium trioxide is probably polymeric.<sup>150,151</sup>

Selenium trioxide shows the typical properties of a Lewis acid<sup>152</sup> and forms 1:1 complexes with organic bases<sup>153</sup> such as pyridine,  $\gamma$ -picoline, quinoline, morpholine, and triethylamine in liquid SO<sub>2</sub> or nitromethane. The complexes were found to be of donor–acceptor type, and IR spectroscopy suggests that selenium is coordinated via the nitrogen atom of the tertiary base. It has also been confirmed that the tetrameric ring of SeO<sub>3</sub> is retained in the adducts.

Lewis-base characteristics are also exhibited by SeO<sub>3</sub>. Reaction with arsenic or antimony chlorides and selenium trioxide in liquid SO<sub>2</sub> produces SeO<sub>3</sub>·AsCl<sub>3</sub>, SeO<sub>3</sub>·SbCl<sub>3</sub>, SeO<sub>3</sub>·SbCl<sub>5</sub>, and 2SeO<sub>3</sub>·AsCl<sub>3</sub>, and the existence of 2SeO<sub>3</sub>·SbCl<sub>3</sub> has been assumed from conductometric measurements.<sup>154</sup> These crystalline adducts are stable below –20 °C. According to the Raman spectra of SeO<sub>3</sub>·AsCl<sub>3</sub> and 2SeO<sub>3</sub>·AsCl<sub>3</sub> the oxygen atom of selenium trioxide is the donor in these complexes and the As atom is the electron-pair acceptor.<sup>155</sup> A thermogravimetric and gas-volumetric study<sup>156</sup> has shown that the thermal decomposition of SeO<sub>3</sub> takes place in two stages, with the formation of an intermediate pentoxide and the evolution of oxygen. It was also observed that SeO<sub>3</sub> begins to decompose at a lower temperature in a nitrogen atmosphere than in oxygen.

#### 4.4 Diselenium Pentoxide

Se<sub>2</sub>O<sub>5</sub> is formed as an intermediate during the thermal two-stage decomposition of SeO<sub>3</sub>.<sup>157</sup> This has been confirmed by a thermoanalytical study and measurements of the evolved oxygen (equations 35 and 36).<sup>156</sup>

Diselenium pentoxide can also be formed as a product in the reaction of selenium dioxide difluoride with SeO<sub>2</sub>. Measurements of molten Se<sub>2</sub>O<sub>5</sub> suggest that [SeO]<sup>+</sup> and [SeO<sub>4</sub>]<sup>2–</sup> ions are present.<sup>157</sup> The structure of crystalline Se<sub>2</sub>O<sub>5</sub> is that of a linear polymer with alternating Se<sup>IV</sup> and Se<sup>VI</sup> atoms (12), which has been confirmed by means of Raman spectroscopy.

#### 4.5 Selenium Oxide Halides

##### 4.5.1 SeOF<sub>2</sub>, SeOCl<sub>2</sub>, and SeOBr<sub>2</sub>

SeOF<sub>2</sub> has a trigonal pyramidal structure (C<sub>s</sub> symmetry), as shown by microwave studies<sup>158,159</sup> and supported by the spectroscopic investigations of gaseous, liquid, and dissolved and solid SeOF<sub>2</sub>.<sup>160–163</sup> In the gaseous state it is monomeric, as in the liquid, although there is some degree of intermolecular interaction. Fluorine and oxygen bridges are formed in the condensed phases, as confirmed by an X-ray structure determination.<sup>164</sup> Figure 11 shows the projection of the crystal structure of SeOF<sub>2</sub>. SeOF<sub>2</sub> reacts with Lewis acids such as NbF<sub>5</sub>, forming adducts of the type SeOF<sub>2</sub>·NbF<sub>5</sub>.<sup>165</sup> The structure is reproduced in Figure 12.

KSeOF<sub>3</sub> is formed exothermally by reaction of SeOF<sub>2</sub> and KF.<sup>166</sup> The spectra confirm the expected geometry with two fluorine atoms at the apices of a pseudotrigonal bipyramid, in agreement with the prediction of the Valence Shell Electron Pair Repulsion (VSEPR) model.<sup>167</sup>

Like SeOF<sub>2</sub>, SeOCl<sub>2</sub> molecules have a tendency to associate.<sup>168</sup> The monomers are in equilibrium with (SeOCl<sub>2</sub>)<sub>2</sub> dimers in CS<sub>2</sub> solution. SeOCl<sub>2</sub> displays Lewis properties similar to other SeOX<sub>2</sub> compounds (X = F, Cl, Br, OMe, OEt). In donor–acceptor complexes of the type D → SeOX<sub>2</sub>, the Se atom always acts as the acceptor.<sup>166</sup> On the other

Figure 11 Projection of the crystal structure of SeOF<sub>2</sub>

Figure 12 Atomic arrangement in SeOF<sub>2</sub>·NbF<sub>5</sub>

hand, in complexes of the type  $X_2SeO \rightarrow A$  the O atom is always the donor.<sup>169–172</sup> Reactions of  $SeOCl_2$  with  $S_2O_6F_2$  and  $BrSO_3F$  yield, for example, a liquid of formula  $SeO(SO_3F)_2$  as a product of both reactions.<sup>173</sup> This compound shows a partial temperature-dependent dissociation (equation 37). More recently,  $SeOCl_2$  has been used as a selenium transfer agent.<sup>174</sup>

Equimolar mixtures of  $SeOCl_2$  and  $SeOF_2$  react to form  $SeOClF$ , which is shown by  $^{77}Se$  NMR<sup>175</sup> and Raman spectroscopy.<sup>163</sup> The reaction of  $SeOCl_2$  with an equimolar amount of  $SeOBr_2$  leads to red–orange liquid  $SeOBrCl$ .<sup>163,175</sup>

The  $SeOBr_2$  molecule has a pyramidal structure ( $C_s$  symmetry), by analogy to  $SeOF_2$  and  $SeOCl_2$ .<sup>163</sup> In the crystal structure, trigonal pyramidal  $SeOBr_2$  molecules are associated with 3 + 3 coordinated selenium to polymeric double chains by oxygen and bromine bridges.<sup>176</sup>

#### 4.5.2 $SeO_2F_2$

$SeO_2F_2$  is a very reactive gas, in contrast to  $SO_2F_2$ , due to the high oxidation power of selenium(VI) and the imperfect steric screening of the selenium atom by only four ligand atoms.<sup>177</sup>  $SeO_2F_2$  has been used as a starting compound for the preparation of a large number of selenium–fluorine compounds. It reacts with dialkyl selenates to yield alkyl esters of fluoroselenic acid<sup>178</sup> and with  $N_2O_3$  and  $N_2O_4$  to yield nitrosonium and nitronium fluoroselenates.<sup>179</sup> When being fluorinated by  $HSO_3F$ ,  $HOSeF_5$  is formed.<sup>180</sup>

#### 4.5.3 $SeOF_4$ and $Se_2O_2F_8$

$SeOF_4$  is prepared by vacuum decomposition of pure sodium pentafluoroorthoselenate (equation 38). The volatile rather unstable product is trapped at  $-196^\circ C$ .<sup>181,182</sup>

It can be assumed that  $SeOF_4$  occurs as an intermediate in the decomposition of  $As(OSeF_5)_3$ ,<sup>183</sup>  $Ti(OSeF_5)_4$ ,<sup>184</sup> or  $LiOSeF_5$ <sup>185</sup> since the stable dimer of  $SeOF_4$  is formed. In very small amounts,  $SeOF_4$  is detected in the thermal decomposition of its dimer,  $Se_2O_2F_8$ , between 200 and  $350^\circ C$ .<sup>186,187</sup>

The  $SeOF_4$  molecule is distorted trigonal bipyramidal, as shown by the IR, Raman,<sup>181</sup> and  $^{19}F$  NMR spectra.<sup>181,182</sup> It is one of the few known hexavalent selenium compounds with fivefold coordination.<sup>182</sup> At temperatures above  $-100^\circ C$  the compound dimerizes to  $Se_2O_2F_8$  (equation 39).<sup>181,182</sup> The

Figure 13 Molecular structure of  $Se_2O_2F_8$

compound is also prepared by pyrolysis of  $NaOSeF_5$  via the intermediate formation of  $SeOF_4$ . The structure consists of two octahedra connected by a common O–O edge with a planar four-membered ring (Figure 13).<sup>188</sup> The dimer has only a slight tendency to split into the monomer even at elevated temperature.

## 5 HALOSELENATES

### 5.1 Haloselenates(IV)

The nucleophilic stepwise degradation of the tetrameric  $Se_4X_{16}$  leads to tri-, di-, and mononuclear haloselenates(IV) (Figure 14).<sup>8</sup> In the case of the cubane-like  $Se_4Cl_{16}$ , the selenium atoms form three strong terminal bonds and three longer bridging bonds so that the bonding is close to an ionic formulation,  $[(SeCl_3^+)_4(Cl^-)_4]$ . As a general reaction scheme, it can be proposed that  $Cl^-$  ions attack the tetramer, eliminating one or two  $SeCl_3^+$  groups in the form of neutral  $SeCl_4$  species (equations 40 and 41). These products are obtained by reaction of stoichiometric amounts of the tetrahalides with  $R^+X^-$  (see

Figure 14 Degradation of the cubane-like tetrameric chalcogen(IV) halides exemplified by  $Se_4Cl_{16}$

above) in organic solvents with low polarity.

### 5.1.1 Mononuclear Anions

The existence of  $[\text{SeF}_6]^{2-}$  is doubtful because  $\text{SeF}_4$  forms only  $[\text{SeF}_5]^-$  anions with alkali fluorides.<sup>101</sup> The pentachloroselenate ion is present in a hydrochloric acid solution of selenium oxide at  $0^\circ\text{C}$ <sup>189</sup> and in solid  $[\text{Et}_4\text{N}][\text{SeCl}_5]$  or  $[\text{Ph}_4\text{As}][\text{SeCl}_5]$ .<sup>190</sup>

The hexahaloselenates(IV)  $[\text{SeX}_6]^{2-}$  ( $\text{X} = \text{Cl}, \text{Br}$ ) are the end-products of the nucleophilic degradation of the tetrahalides<sup>8,61</sup> (see Figure 14). The more or less ideal octahedral symmetry of these 14-electron  $\text{SeX}_6\text{E}$  systems cannot be described using simple models. They had been quoted as exceptions from the VSEPR theory.<sup>167,191–193</sup> From spectroscopic and theoretical studies, their bonding, structure, and their dynamic properties are well investigated.<sup>61,194,195</sup> Models to describe them extend from a simple  $4p^34d^25s$  hybridization scheme,<sup>196</sup> with the inert pair shielding the bonding electrons, up to a molecular orbital-based model of three orthogonal three-center–four-electron bonds.<sup>197</sup>

### 5.1.2 Dinuclear and Trinuclear Anions

Decahaloselenates(IV) and tridecaloselenates(IV) were isolated in salts such as  $[\text{Ph}_4\text{As}]_2[\text{Se}_2\text{Cl}_{10}]$ ,<sup>198</sup>  $[(\text{C}_{14}\text{H}_{13}\text{ClN}_3)_2[\text{Se}_2\text{Cl}_{10}]\cdot 2\text{MeCN}]$ ,<sup>199</sup>  $[\text{Et}_4\text{N}]_2[\text{Se}_2\text{Br}_{10}]$ ,<sup>8</sup>  $[\text{Ph}_3\text{C}][\text{Se}_3\text{Cl}_{13}]$ ,<sup>200</sup> and  $[\text{Ph}_3\text{C}][\text{Se}_3\text{Br}_{13}]$ .<sup>200</sup> The dinuclear  $[\text{Se}_2\text{X}_{10}]^{2-}$  structure consists of edge-sharing distorted octahedra. Also, as a fragment of  $\text{Se}_4\text{X}_{16}$  cubes, the anions  $[\text{Se}_3\text{X}_{13}]^-$  consist of three edge-sharing octahedra with a central triply bridging chlorine or bromine atom (Figure 15).<sup>200</sup>

Figure 15  $[\text{Se}_3\text{Cl}_{13}]^-$  ion in  $[\text{Ph}_3\text{C}][\text{Se}_3\text{Cl}_{13}]$

Figure 16  $[\text{Se}_2\text{Br}_9]^-$  ion in the crystal structure of  $[\text{EtPh}_3\text{P}][\text{Se}_2\text{Br}_9]\cdot\text{CH}_2\text{Cl}_2$

The series of the decahaloselenates(IV) clearly demonstrates the stereochemical influence of the inert pair as a function of the halogen atom. The alkali metal pentafluoroselenates(IV) contain only the monomeric  $\psi$ -octahedral  $[\text{SeF}_5]^-$  anions.<sup>101,102</sup>

If the degradation reaction of the tetramers is performed at slightly lower temperatures with very slow addition of halide as the nucleophilic agent, unexpected dinuclear nonahaloselenates(IV) are obtained. Their existence, together with evidence from their Raman spectra,<sup>198</sup> indicates the presence of an equilibrium between  $[\text{Se}_2\text{X}_{10}]^{2-}$  and  $[\text{Se}_2\text{X}_9]^-$  in aprotic solutions (equation 42).

The  $[\text{Se}_2\text{X}_9]^-$  ions were isolated in  $[\text{Ph}_4\text{As}][\text{Se}_2\text{Cl}_9]$ ,<sup>198</sup>  $[\text{EtPh}_3\text{P}][\text{Se}_2\text{Br}_9]\cdot\text{CH}_2\text{Cl}_2$ ,<sup>201</sup> and in the double salts  $[\text{Et}_4\text{N}]_4[\text{Se}_2\text{Br}_{10}(\text{Se}_2\text{Br}_9)_2]$ <sup>188</sup> and  $[\text{Et}_4\text{N}]_4[\text{Se}_2\text{Cl}_{10}(\text{Se}_2\text{Cl}_9)_2]$ .<sup>8,198</sup> In Figure 16, the  $[\text{Se}_2\text{Br}_9]^-$  anion is shown.<sup>201</sup> These nonahaloselenates(IV) contain three  $\mu$ -bridging halogens, resulting in face-sharing of the two octahedral halves of the molecule.

### 5.1.3 Polynuclear Anions

$[\text{S}_4\text{N}_3]_n[\text{SeCl}_5]_n$ <sup>202</sup> was obtained by diffusion of  $\text{Se}_2\text{Cl}_2$  and  $\text{S}_4\text{N}_4$  in  $\text{SOCl}_2$  for several days. It contains polymeric  $[\text{SeCl}_5^-]_n$  chains built from *cis* corner-sharing octahedra, resulting in  $\text{SeCl}_{4+2}$  coordination (Figure 17a).

A compound with the empirical composition  $[\text{Me}_3\text{NH}]_2[\text{SeBr}_8]$ <sup>4,203</sup> was formed from  $\text{SeBr}_4$  and trimethylammonium bromide in boiling aqueous  $\text{HBr}$ . It contains distorted  $[\text{SeBr}_6]^{2-}$  anions which are in bonding contact to two *cis*-coordinated  $\text{Br}_2$  molecules to form endless chains of composition  $[\text{SeBr}_6^{2-}\cdot\text{Br}_2]_n$  (Figure 17b). The bond length in the  $\text{Br}_2$  unit is significantly elongated compared to the free molecule, and the distortion of the  $\text{SeBr}_6$  octahedron reflects the effect of intermolecular bonding.

**Figure 17** (a) Section of the polymeric  $[\text{SeCl}_5^-]_n$  chain; (b) Section of the polymeric  $[\text{SeBr}_6^{2-} \cdot \text{Br}_2]_n$  ion

## 5.2 Haloselenates(II)

### 5.2.1 Mononuclear and Dinuclear Anions

By symproportionation of elemental selenium and  $\text{SeCl}_4$  in polar protic solvents,  $[\text{SeCl}_4]^{2-}$  and  $[\text{Se}_2\text{Cl}_6]^{2-}$  can be stabilized. They crystallize with voluminous organic cations (with  $\text{SeCl}_2:\text{RCl}$  ratios of 1:2 and 1:1) (equations 43–45).

Using large organosubstituted counteranions the anions could be isolated as  $[\text{Ph}_3(\text{C}_2\text{H}_4\text{OH})\text{P}]_2[\text{SeCl}_4] \cdot \text{MeCN}$  and  $[\text{Ph}_4\text{P}]_2[\text{Se}_2\text{Cl}_6]$ .<sup>204</sup> Also, the  $\text{S}_4\text{N}_3^+$  cation is able to stabilize  $[\text{Se}_2\text{Cl}_6]^{2-}$  in  $[\text{S}_4\text{N}_3]_2[\text{Se}_2\text{Cl}_6]$ .<sup>202</sup> Mononuclear planar haloselenates(II) are square-planar ( $\psi^2$ -octahedral) as predicted from VSEPR model considerations for these  $\text{XY}_4\text{E}_2$  systems, which are isoelectronic with  $\text{ICl}_4^-$  or  $\text{XeF}_4$ . Their bonding can be described as a system of two four-electron–three-center bonds with a formal MO bond order of 0.5. The dinuclear planar  $\text{X}_2\text{Y}_6^{2-}$  structure (isoelectronic with  $\text{I}_2\text{Cl}_6$ ) consists of two edge-sharing distorted  $\text{XY}_4$  squares. Tetrabromoselenate(II),  $[\text{SeBr}_4]^{2-}$ , and hexabromodiselenate(II),  $[\text{Se}_2\text{Br}_6]^{2-}$ , are formed in equilibrium mixtures of  $\text{SeOBr}_2$  and/or  $\text{SeBr}_4$  and their thermal reaction products in moderately polar organic solvents

**Figure 18** Structures of  $[\text{SeBr}_4]^{2-}$  and  $[\text{Se}_2\text{Br}_6]^{2-}$

(equations 46–49).<sup>205,206</sup>

The structures of  $[\text{SeBr}_4]^{2-}$  and  $[\text{Se}_2\text{Br}_6]^{2-}$  are shown in Figure 18. From vibrational spectra it was concluded that the dimers dissociate in solution and form discrete T-shaped trihaloselenates(II).<sup>207</sup>

### 5.2.2 Tri-, Tetra-, and Pentanuclear Anions

Trinuclear  $[\text{Se}_3\text{Br}_8]^{2-}$  was obtained in a 2-methyl propionitrile solution of  $\text{SeBr}_4$ , Se, and  $\text{CuBr}$  as the copper(I) salt  $[(i\text{-PrCN})_4\text{Cu}]_2[\text{Se}_3\text{Br}_8]$ .<sup>203,208</sup> The structure consists of a triangular arrangement of three planar  $\text{SeBr}_4$  groups sharing a common edge (Figure 19a).

The tetranuclear  $[\text{Se}_4\text{Br}_{14}]^{2-}$  anion was isolated as the ammonium salt  $[\text{Me}_3\text{PhN}]_2[\text{Se}_4\text{Br}_{14}]$ <sup>209</sup> and as the phosphonium salt  $[\text{EtPh}_3\text{P}]_2[\text{Se}_4\text{Br}_{14}]$ .<sup>208</sup> In these tetranuclear molecules, planar dinuclear  $\text{Se}_2\text{Br}_6$  units are linked through two unusual nearly linear  $\text{Se}-\text{Br}-\text{Se}$  bridges. The bridging bromine atoms have the formal oxidation state +1. The  $\text{Se}-\text{Br}-\text{Se}$  bond angles are  $175.9^\circ$ <sup>209</sup> and  $176.1^\circ$ <sup>208</sup> (Figure 19b). If the ratio of  $\text{SeBr}_2$  to  $\text{R}^+\text{Br}^-$  in the equilibrated

**Figure 19** (a)  $[\text{Se}_3\text{Br}_8]^{2-}$  anion, (b)  $[\text{Se}_4\text{Br}_{14}]^{2-}$  anion, and (c)  $[\text{Se}_5\text{Br}_{12}]^{2-}$  anion

reaction mixture is more than 2.5, the pentanuclear  $[\text{Se}_5\text{Br}_{12}]^{2-}$  anion is formed.<sup>208</sup> It has  $D_{2h}$  symmetry and is composed of five planar  $\text{SeBr}_4$  groups. Two pairs of two peripheral  $\text{SeBr}_4$  units share one edge with one another and with the central unit (see Figure 19c). Because of the long Se–Br bonds from the terminal  $\text{SeBr}_2$  groups to the  $\mu_3$ -Br ligands, the bonding

can also be approximated by the structural formula  $[(\text{SeBr}_4^{2-})_5(\text{SeBr}_2)_4]$ .

### 5.3 Mixed-Valence Haloselenates(II/IV)

From the complex reaction mixture of the redox system  $\text{SeBr}_4/\text{SeBr}_2/\text{Se}/\text{Br}^-$  in aprotic solvents, di-, tri-, and tetranuclear mixed-valence bromoselenates(II/IV) containing selenium in both oxidation states +2 and +4 were prepared:  $[\text{Se}_2\text{Br}_8]^{2-}$ ,  $[\text{Se}_3\text{Br}_{10}]^{2-}$ , and  $[\text{Se}_4\text{Br}_{12}]^{2-}$  (Figure 20).

In the  $[\text{Se}^{\text{II}}\text{Se}^{\text{IV}}\text{Br}_8]^{2-}$  anion,<sup>210,211</sup> an octahedral  $\text{Se}^{\text{IV}}\text{Br}_6$  group shares one edge with a square-planar  $\text{Se}^{\text{II}}\text{Br}_4$  group. This coordination gives a clear assignment of the oxidation state of each selenium atom. The dihedral angles between the  $\text{Se}^{\text{II}}\text{Br}_4$  plane and the basal plane of the  $\text{Se}^{\text{IV}}\text{Br}_6$  octahedron are  $34^\circ$ <sup>210</sup> and  $57^\circ$ .<sup>211</sup>

By formal addition of a  $\text{SeBr}_2$  group to this  $[\text{SeBr}_8]^{2-}$  anion, the trinuclear decabromotriselenate(II/IV)  $[\text{Se}_2^{\text{II}}\text{Se}^{\text{IV}}\text{Br}_{10}]^{2-}$  is formed, which was isolated as the *n*-propylammonium salt  $[(n\text{-Pr})_4\text{N}]_2[\text{Se}_3\text{Br}_{10}]$ .<sup>210</sup> In the centrosymmetric anion (see Figure 20b), a central  $\text{Se}^{\text{IV}}\text{Br}_6$  octahedron is linked through two trans edges to two square-planar  $\text{Se}^{\text{II}}\text{Br}_4$  groups with dihedral angles of  $22^\circ$  between the equatorial planes.

In the  $[\text{Se}_3^{\text{II}}\text{Se}^{\text{IV}}\text{Br}_{12}]^{2-}$  ion,<sup>210</sup> two  $\text{SeBr}_2$  moieties are coordinated via *cis* edges to the octahedral central  $\text{Se}^{\text{IV}}\text{Br}_6$  unit. A third  $\text{SeBr}_2$  group bridges one of the  $\text{Se}^{\text{IV}}\text{BrSe}^{\text{II}}\text{Br}$  four-membered rings such that a short Se–Se distance of 3.335 Å results between Se(4) and Se(2) (see Figure 20c), indicating a

**Figure 20** Mixed-valence bromoselenate(II/IV) anions: (a)  $[\text{Se}_2\text{Br}_8]^{2-}$  in  $[\text{Et}_4\text{N}]_2[\text{Se}_2\text{Br}_8]$ ; (b)  $[\text{Se}_3\text{Br}_{10}]^{2-}$  in  $[(n\text{-Pr})_4\text{N}]_2[\text{Se}_3\text{Br}_{10}]$ ; (c)  $[\text{Se}_4\text{Br}_{12}]^{2-}$  in  $[\text{Ph}_4\text{P}]_2[\text{Se}_4\text{Br}_{12}]\cdot\text{CH}_2\text{Cl}_2$

weak bonding interaction. Se(2) thereby completes the square-planar coordination geometry of Se(4).

The diamagnetic mixed-valence bromoselenates(II/IV) are to be assigned to class I in the Robin–Day scheme.<sup>212</sup> From the structural behavior, a significant valence exchange is not to be expected. The coordination geometries are always clear indications of different oxidation numbers.

## 6 OXOHALOSELENATES

### 6.1 Oxohaloselenates(IV)

Numerous oxohaloselenates(IV) with strong Se=O bonding are known. Three classes of these compounds can be prepared with stoichiometric compositions of  $[\text{SeO}_2\text{X}]^-$ ,  $[\text{SeOX}_3]^-$ , and  $[\text{SeOX}_4]^{2-}$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}$ ).<sup>8,213–216</sup> The methods of preparation use nucleophilic addition reactions in different stoichiometric proportions of  $\text{SeOF}_2$ ,  $\text{SeOCl}_2$ , or  $\text{SeOBr}_2$  (or  $\text{SeO}_2$  for oxygen-rich species, or  $\text{SeX}_4$  + small amounts of  $\text{H}_2\text{O}$ ) with the halide in aprotic solvents.  $[\text{SeO}_2\text{X}]^-$  species had been predicted from spectroscopic considerations<sup>190</sup> and were confirmed by the preparation and structure of crystalline  $[\text{Me}_4\text{N}][\text{SeO}_2\text{Cl}]$  and  $[\text{Ph}_4\text{P}][\text{SeO}_2\text{Br}]$ .<sup>176</sup> The structures of  $[\text{SeO}_2\text{Cl}]^-$  and  $[\text{SeO}_2\text{Br}]^-$  anions in these salts are shown in Figure 21.  $[\text{SeO}_2\text{Cl}]^-$  is mononuclear, trigonal pyramidal, as expected for an  $\text{XY}_2\text{Y}'\text{E}$  system. The closely related  $[\text{SeO}_2\text{Br}]^-$ , however, is associated through bridging bromine to polymeric chains. This shows once more the stereochemical flexibility and wide variability of the chalcogen inert-pair system as a function of the electronic environment.

This variability is also evident in the oxotrihaloselenates(IV). With different counteranions, three isomers of the  $[\text{SeOX}_3]^-$  anion could be prepared and structurally characterized (Figure 22).<sup>8</sup> A polymeric arrangement of  $[\text{SeOX}_3^-]_n$  chains is found in  $[\text{C}_9\text{H}_8\text{NO}][\text{SeOCl}_3]$ .<sup>216</sup> The chains consist of distorted square  $\text{SeOCl}_4$  pyramids with apical Se=O bonds (1.59 Å), two *cis* chlorines at 2.25 Å, and two bridging Cl at 2.96 and 2.99 Å from the selenium atom.

**Figure 21** The two isomeric  $[\text{SeO}_2\text{Br}]^-_n$  and  $[\text{SeO}_2\text{Cl}]^-$  ions in (a)  $[\text{Ph}_4\text{P}][\text{SeO}_2\text{Br}]$  and (b)  $[\text{Me}_4\text{N}][\text{SeO}_2\text{Cl}]$

**Figure 22** The three isomeric forms of oxotrichloroselenates(IV)

**Figure 23** (a) Structure of the monomeric  $[\text{SeOCl}_3]^-$  ion in  $[\text{Ph}_4\text{As}][\text{SeOCl}_3]$  and (b) of the  $[\text{SeOCl}_3^-]_2$  ion in  $[\text{Ph}_4\text{P}][\text{SeOCl}_3]$

A monomeric  $[\text{SeOCl}_3]^-$  anion with a trigonal bipyramidal structure is present in  $[\text{Ph}_4\text{As}][\text{SeOCl}_3]$ .<sup>217</sup> According to the VSEPR model, the oxygen (Se=O double bond) and the lone pair are located in the equatorial positions (Figure 23a). The third isomer is dinuclear; it can be isolated in the salts  $[\text{Et}_4\text{N}][\text{SeOCl}_3]$ ,<sup>217</sup>  $[\text{Ph}_4\text{P}][\text{SeOCl}_3]$ ,  $[\text{Ph}_4\text{P}][\text{SeOBr}_3]$ , and  $[\text{Ph}_4\text{As}][\text{SeOBr}_3]$ .<sup>218</sup> The centrosymmetric dianions consist of two edge-sharing tetragonal pyramidal  $\text{SeOX}_4$  units with the inert pair at the selenium atom in trans positions to the strongly bonded axial oxygen atom (Figure 23b).

By formal exchange of one halogen for an oxygen atom, anions of the type  $[\text{SeO}_2\text{X}_2]^{2-}$  are formed. The potassium salt  $\text{K}_2\text{SeO}_2\text{F}_2$ , which can be obtained by heating  $\text{KSeO}_2\text{F}$

with an excess of KF to  $\approx 300^\circ\text{C}$  or by decomposing  $\text{KSeO}_2\text{F}$  in vacuum at  $180^\circ\text{C}$ , contains the  $[\text{SeO}_2\text{F}_2]^{2-}$  dianion. It is  $\psi$ -trigonal bipyramidal ( $C_{2v}$  symmetry) with the lone pair and the oxygen atoms in equatorial positions.<sup>219</sup>

The  $[\text{SeOCl}_4]^{2-}$  anion is formed by nucleophilic attack of  $\text{SeOCl}_2$  by two  $\text{Cl}^-$ :

A regular pyramidal anion  $[\text{SeOCl}_4]^{2-}$  is observed in the pyridinium double salt  $[(\text{C}_5\text{H}_5\text{NH})_4(\text{H}_3\text{O})][(\text{SeOCl}_4)_2\text{Cl}] \cdot 11\text{H}_2\text{O}$ <sup>8,220</sup> ( $\text{Se}=\text{O}$  1.602 Å;  $\text{Se}-\text{Cl}$  2.482 Å). In the dipyridinium salt  $[\text{C}_{10}\text{H}_8\text{N}_2\text{H}_2]_2[\text{SeOCl}_4]^{2-}$ <sup>221</sup> ( $\text{Se}=\text{O}$  1.63 Å;  $\text{Se}-\text{Cl}$  2.25, 2.48, 2.48, 2.99 Å), the anions are distorted by participation of one of the Cl ligand atoms in strong  $\text{Se}-\text{Cl} \cdots \text{H}-\text{N}$  hydrogen bridges to the cation. The ion is also present in  $[\text{Et}_4\text{N}]_2[\text{SeOCl}_4]$ , and  $[\text{Ph}_4\text{As}]_2[\text{SeOCl}_4]$ .<sup>222</sup>

A polynuclear  $[\text{Cl}_2(\text{SeOCl}_2)_{10}]^{2-}$  unit is formed in  $[\text{Me}_4\text{N}]_2[\text{Cl}_2(\text{SeOCl}_2)_{10}]$ .<sup>223</sup> The two chloride ions are solvated by 10  $\text{SeOCl}_2$  molecules so that each  $\text{Cl}^-$  is octahedrally surrounded by six  $\text{SeOCl}_2$  units, two of them sharing an adjacent octahedron (Figure 24).

## 6.2 Oxohaloselenates(VI)

The anion  $[\text{SeO}_3\text{F}]^-$  is present in the compounds  $\text{MSeO}_3\text{F}$  ( $\text{M}$  = alkali metal,  $\text{NH}_4$ , Ag, Tl, Cu, Zn, Cd, Co, Ni). It also occurs in the salts  $[\text{NO}][\text{SeO}_3\text{F}]$ <sup>179</sup> and  $[\text{NO}_2][\text{SeO}_3\text{F}]$ .<sup>224</sup> The corresponding acid  $\text{HSeO}_3\text{F}$  is a clear, colorless liquid which hydrolyzes immediately.<sup>225</sup> It decomposes even at room temperature (equation 51).

**Figure 24** The arrangement of  $\text{SeOCl}_2$  molecules around chloride ions in  $[\text{Me}_4\text{N}]_2[\text{Cl}_2(\text{SeOCl}_2)_{10}]$  (distances in Å)

**Figure 25** The structure of the  $\text{Xe}[\text{OSeF}_5]_2$  molecule

The Raman and IR spectra of  $[\text{NO}_2][\text{SeO}_3\text{F}]$  and  $\text{K}[\text{SeO}_3\text{F}]$  can be assigned on the assumption of  $C_{3v}$  symmetry for the  $[\text{SeO}_3\text{F}]^-$  anion.<sup>224</sup>

Pentafluoroselenic(VI) acid,  $\text{HSeF}_5$ , was unexpectedly discovered during experiments to prepare the unknown  $\text{SeOF}_4$ .<sup>202</sup> It is best prepared from  $\text{SeO}_2\text{F}_2$ ,  $\text{HOSO}_2\text{F}$ , and HF or  $\text{KHF}_2$  (equation 52).

The anion  $[\text{OSeF}_5]^-$  occurs in the pentafluoroorthoselenates  $\text{MOSeF}_5$  ( $\text{M}$  = Li, K, Rb, Cs,  $\text{NH}_4$ ,<sup>226</sup> Na,<sup>181,226</sup>  $\text{NO}_2$ <sup>183,227</sup>). The structure is octahedral, as derived from  $^{19}\text{F}$  NMR, IR, and Raman spectra. The  $\text{OSeF}_5$  group can best be characterized as a pseudohalogen or, more specifically, as a pseudofluorine. According to its reactions, this unit is more electronegative than fluorine. This is in line with the observation that the  $\text{OSeF}_5$  groups in  $\text{F}_n\text{I}[\text{OSeF}_5]_{5-n}$  occupy only equatorial positions.<sup>228</sup> The similarity to fluorine as a ligand is also shown in the ability of  $[\text{OSeF}_5]^-$  to form the most stable xenon compound  $\text{Xe}[\text{OSeF}_5]_2$ <sup>229</sup> (Figure 25) besides the simple fluoride.

The extreme electronegativity of the  $\text{OSeF}_5$  group is a result of the inductive effect of the five fluorines, thus additionally promoting  $p_\pi-d_\pi$  back-bonding from oxygen to the selenium atom.

## 7 SELENIUM AND NITROGEN

### 7.1 Selenium Nitrides

#### 7.1.1 The $\text{SeN}$ Radical

Selenium nitride,  $\text{SeN}$ , is formed by the reaction of selenium or selenium chlorides  $\text{Se}_2\text{Cl}_2$  or  $\text{SeCl}_4$ <sup>61</sup> with active nitrogen produced by a high frequency discharge. To date, only the electron band spectra have been investigated.

#### 7.1.2 Tetraselenium Tetranitride, $\text{Se}_4\text{N}_4$

$\text{Se}_4\text{N}_4$  is prepared by ammonolysis of selenium tetrahalides,<sup>230–235</sup> diselenium dichloride,<sup>236</sup> selenium dioxide,<sup>232</sup> or diethyl selenite.<sup>226</sup> It is rather unstable and decomposes explosively on heating or by sudden impact.

Figure 26 Structure of the  $\text{Se}_4\text{N}_4$  molecule

In alkaline medium it is hydrolyzed to ammonia, elemental selenium, and selenium–oxygen compounds.

$\text{Se}_4\text{N}_4$  exists in at least two crystal modifications. The reaction of liquid  $\text{NH}_3$  and  $\text{SeCl}_4$ , or  $\text{SeBr}_4$ , in an autoclave<sup>232</sup> yields crystals of the stable modification,<sup>237</sup> which is not isostructural with  $\text{S}_4\text{N}_4$ . It consists of discrete cage-like  $\text{Se}_4\text{N}_4$  molecules. The eight-membered ring is puckered, the four selenium atoms being situated at the corners of a tetrahedron with the nitrogen atoms in a plane (Figure 26).

The metastable modification reverts to the first on heating.<sup>238</sup> Compounds of the type  $(\text{SeNSeNSe})_n(\text{AsF}_6)_2$ , where  $n$  is 1 or 2, have been prepared by the reaction of stoichiometric quantities of  $\text{Se}_4(\text{AsF}_6)_2$  ( $n = 2$ ) or  $\text{AsF}_5$  ( $n = 1$  and 2) with  $\text{Se}_4\text{N}_4$  in liquid sulfur dioxide.<sup>239</sup> ESR spectroscopy showed that  $(\text{SeNSeNSe})_2(\text{AsF}_6)_2$  contains the stable  $7\pi$  radical  $(\text{SeNSeNSe})^{\cdot+}$  in solution while Raman and IR spectroscopy identified the  $6\pi$   $(\text{SeNSeNSe})^{2+}$  cation in  $(\text{SeNSeNSe})(\text{AsF}_6)_2$ . The structures of the solid species were characterized by X-ray structure determination. The reaction of  $\text{Se}_4\text{N}_4$  with  $[\text{PtCl}_2(\text{PMe}_2\text{Ph})]_2$  in  $\text{CHCl}_3$  gives  $\text{Pt}(\text{Se}_3\text{N})\text{Cl}(\text{PMe}_2\text{Ph})$  as the first example of a metal selenium–nitrogen complex. It contains the square-planar bidentate  $\text{Se}_3\text{N}^-$  ligand coordinated through two selenium atoms.<sup>240</sup>

### 7.1.3 $\text{Se}_4\text{N}_2$

In comparison to  $\text{Se}_4\text{N}_4$ , the recently synthesized  $\text{Se}_4\text{N}_2$  molecule<sup>241</sup> is thermally more stable. It is formed by the reaction of  $\text{Se}_2\text{Cl}_2$  with trimethylsilyl azide in  $\text{CH}_2\text{Cl}_2$  (equation 53).

According to its IR spectra the molecule has  $C_s$  symmetry with a chair configuration (13).

Two donor–acceptor complexes,  $[\text{SnCl}_4(\text{Se}_4\text{N}_2)_2]$  and  $[\text{TiCl}_4(\text{Se}_4\text{N}_2)]$ , have been prepared by the reaction of  $\text{Se}_4\text{N}_2$  with  $\text{SnCl}_4$  and  $\text{TiCl}_4$ , respectively, in  $\text{CH}_2\text{Cl}_2$  suspensions.<sup>242</sup> According to IR and  $^{119}\text{Sn}$  Mössbauer spectra, in the tin complex both  $\text{Se}_4\text{N}_2$  molecules are bonded with one of the nitrogen atoms at the tin atom in trans positions (14), whereas in the titanium complex both nitrogen atoms are assumed to be bonded in a chelating fashion at the titanium atom (15).

The reaction of tungsten hexachloride with  $\text{Se}_4\text{N}_2$  leads to  $[\text{WCl}_4(\text{NSeCl})]_2$ , which reacts with pyridine to form  $[\text{WCl}_4(\text{NSeCl})\text{py}]$ , and with tetraphenylphosphonium chloride to form  $\text{PPh}_4[\text{WCl}_5(\text{NSeCl})]$ .<sup>243</sup> The  $[\text{WCl}_5(\text{NSeCl})]^-$  ion contains an almost linear  $\text{WNSe}$  group.

### 7.1.4 Selenium Chloride Nitrides

Two stable chloride nitrides of selenium (with formal oxidation state +3 for Se),  $\text{Se}_2\text{NCl}_3$  and  $(\text{Se}_2\text{NCl}_2)(\text{GaCl}_4)$ , have been synthesized.<sup>244</sup> The first structure consists of neutral  $\text{Se}_2\text{NCl}_3$  units. The molecule is nearly planar with two linear  $\text{Cl–Se–Cl}$  moieties connected through a common bridging  $\text{Cl}$  atom. The nitrogen atom forms a second bridge between the two selenium atoms. The mean  $\text{Se–N}$  bond length of 1.738 Å and the  $\text{Se–N–Se}$  bond angle of  $119.9^\circ$  implies the presence of delocalized  $\pi$ -bonds between the Se atoms. The elimination of the bridging  $\text{Cl}$  atom with Lewis acids like  $\text{GaCl}_3$  or  $\text{AlCl}_3$  yields the cation  $\text{Se}_2\text{NCl}_2^+$ ; it is nearly planar. The cation has approximately  $C_{2v}$  symmetry, with  $\text{N–Se}$  bond lengths of 1.695 Å,  $\text{Se–Se}$  distances of 2.147 Å, and bond angles of  $146.6^\circ$  ( $\text{Se–N–Se}$ ) and  $108.3^\circ$  ( $\text{Cl–Se–N}$ ).

### 7.1.5 Related Selenium–nitrogen Rings

Diselenium dichloride,  $\text{Se}_2\text{Cl}_2$ , and seleninyl chloride,  $\text{SeOCl}_2$ , react with a lithium salt of silylated *t*-butylamine with elimination of  $\text{LiCl}$  and  $\text{Me}_3\text{SiCl}$  or of  $\text{LiCl}$ ,  $\text{Me}_3\text{SiCl}$ , and  $(\text{Me}_3\text{Si})_2\text{O}$ , respectively, to form the cyclic compounds  $(t\text{-Bu})_2\text{N}_2\text{Se}_6$  (16), a hexaselenadiazocin, and  $(t\text{-Bu})_6\text{N}_6\text{Se}_9$

(17), a nonaselenahexaazacyclopentadecane. The structures were established by X-ray diffraction.<sup>245</sup>

Another recently synthesized compound with a selenium atom coordinated by three nitrogen atoms is the tricyclic compound  $\text{SeSb}_2\text{Cl}_2(\text{NCMe}_3)_4$ , a product of the reaction between  $[\text{Se}[\text{NCMe}_3(\text{SiMe}_3)]_2]$  and  $\text{SbCl}_3$ .<sup>246</sup> According to an X-ray structure analysis, the six-membered  $\text{SeSb}_2\text{Cl}_2(\text{NCMe}_3)_3$  ring is bonded to the triply bridging  $\text{NCMe}_3$  moiety (Figure 27).

#### 7.1.6 Selenium Imides

Newly available, pure,  $\text{SeCl}_2$ <sup>62</sup> was used, in combination with variable mole ratios of  $t\text{BuNH}_2$ , to prepare the structurally characterized imide compounds, acyclic  $\text{ClSe}[\text{N}(t\text{-Bu})\text{Se}]_1\text{and}_2\text{Cl}$ ,  $\text{Se}_3(\text{N}^t\text{Bu})_2$ ; and by combining  $\text{SeCl}_4$  and  $t\text{BuNH}_2$  with  $\text{SO}_2\text{Cl}_2$  or  $\text{SeOCl}_2$ , cyclic  $t\text{BuNSe}(\mu\text{-}t\text{Bu})_2\text{E}$  ( $\text{E} = \text{SO}_2$  and  $\text{SeO}$ ).<sup>247</sup> The selenium-containing compounds were also studied by  $^{77}\text{Se}$  NMR. The thermal decomposition of  $\text{Se}(\text{NAd})_2$  was studied by  $^{77}\text{Se}$  NMR which indicated the presence of  $\text{Se}_3(\text{NAd})_3$ ,  $\text{Se}(\text{NAd})(\mu\text{-NAd})_2\text{SeO}$  and  $\text{OSe}(\mu\text{-NAd})_2\text{SeO}$ .<sup>248</sup>  $\text{Se}_3(\text{NAd})_2$  was isolated from the

reaction and structurally characterized ( $\text{Se}-\text{Se} = 2.404(1) \text{ \AA}$ ,  $\text{Se}-\text{N} = 1.873(4) \text{ \AA}$ ).<sup>249</sup>

## 7.2 Amides of Selenious and Selenic Acid

### 7.2.1 Selenious Diamide, $\text{SeO}(\text{NH}_2)_2$ , and Related Compounds

Selenious diamide is formed by reaction of ammonia with diethyl selenite or seleninyl bis(dimethylamide) (equation 54).<sup>250</sup>

The compound is sensitive to solvolysis and thermally unstable.  $(\text{NH})_2\text{Se}$  is formed by decomposition above  $-40^\circ\text{C}$ . Using methylamine or ethylenediamine instead of ammonia, seleninyl ethylenediamide,  $(\text{CH}_2\text{NH})_2\text{SeO}$ , can be obtained by an analogous reaction. By the reaction of seleninyl bis(dimethylamide) with seleninyl chloride, a dimethylamide of chloroselenic(IV) acid results (equation 56).

### 7.2.2 Amidoselenic Acid, $\text{HSeO}_3\text{NH}_2$ , and the $\text{SeO}_3\text{NH}_2^-$ Ion

The free acid  $\text{HSeO}_3\text{NH}_2$  has not yet been prepared. The first salt of the acid was  $\text{NH}_4\text{SeO}_3\text{NH}_2$ , obtained by reaction of  $\text{C}_5\text{H}_5\text{N} \cdot \text{SeO}_3$  with  $\text{NH}_3$ .<sup>251</sup> IR spectroscopy suggests  $C_s$  symmetry for the  $\text{SeO}_3\text{NH}_2^-$  ion.<sup>252,253</sup>

In aqueous ammonia,  $\text{SeO}_3\text{NH}_2^-$  anions react with excess  $\text{Ag}^+$  ions to give two modifications of  $\text{AgSeO}_3\text{NAg}_2$ .<sup>254</sup> The crystal structure of  $\alpha\text{-Ag}_3\text{NSeO}_3$  consists of infinite chains of  $\text{O}_3\text{SeNAg}_3$  molecules joined by  $\text{O} \cdots \text{Ag}-\text{N}$  bridges,<sup>255</sup> in agreement with earlier IR results.<sup>256</sup> The molecules have almost regular tetrahedral configurations at each end and the  $\text{Se}-\text{O}$  and  $\text{N}-\text{Ag}$  bonds are almost eclipsed with a dihedral angle of  $11.1^\circ$ .<sup>257</sup>

### 7.2.3 Selenic Diamide, $\text{SeO}_2(\text{NH}_2)_2$

Selenic diamide,  $\text{SeO}_2(\text{NH}_2)_2$ , is formed by reaction of  $\text{SeO}_2\text{F}_2$  and  $\text{NH}_3$  in the gas phase or in inert solvents (e.g.  $\text{CCl}_4$ ) among other selenium(VI)–nitrogen compounds.<sup>177,257</sup> In liquid ammonia,  $\text{SeO}_2(\text{NH}_2)_2$  is thermally unstable (equation 57). It converts at  $-50^\circ\text{C}$  to the ammonium salts of cyclic triselenonylimide and at ambient temperature to the diamidopolyimidoselenic acids (equations 58–60).<sup>258,259</sup> Diamidoselenic acid hydrolyzes in water to form ammonium amidoselenate (equation 61).<sup>258,259</sup>

Figure 27 Structure of  $\text{SeSb}_2\text{Cl}_2(\text{NCMe})_4$

**Figure 28** Molecular structure of  $[\text{SeO}_2\text{N}]_3^{3-}$

### 7.3 Polymeric Anions of Selenonylimide

Selenonylimide,  $\text{SeO}_2\text{NH}$ , has not yet been isolated. The trimeric anion,  $[\text{SeO}_2\text{N}]_3^{3-}$ , occurs in some salts and the tetrameric anion,  $[\text{SeO}_2\text{N}]_4^{4-}$ , was identified by paper chromatography.

#### 7.3.1 The $[\text{SeO}_2\text{N}]_3^{3-}$ Ion

The cyclic triselenonylimide ion,  $[\text{SeO}_2\text{N}]_3^{3-}$ , is present in the salts  $\text{M}_3[\text{SeO}_2\text{N}]_3$  with  $\text{M} = \text{K}$ ,<sup>259–261</sup>  $\text{NH}_4$ ,<sup>258–260</sup>  $\text{Ag}$ ,  $\text{Tl}^+$ .<sup>260</sup> All are highly explosive. The  $[\text{SeO}_2\text{N}]_3^{3-}$  anion in the potassium salt (Figure 28) is a six-membered ring of approximate  $\text{C}_{3v}$  symmetry in a chair configuration with a considerably flattened  $\text{Se}_3\text{N}_3$  skeleton. The Se–N distances indicate  $\text{p}_\pi\text{--d}_\pi$  delocalization over the individual Se–N–Se units.<sup>261</sup>

#### 7.3.2 The $[\text{SeO}_2\text{N}]_4^{4-}$ Ion

The tetraselenonylimide ion,  $[\text{SeO}_2\text{N}]_4^{4-}$ , could only be detected in a paper chromatogram of the reaction products of  $\text{SeO}_2\text{F}_2$  and  $\text{NH}_3$ .<sup>257</sup>

## Glossary

*Ad<sub>E</sub>2 mechanism:* a bimolecular 1,2-addition of an electrophilic reagent to an alkene via a cationic intermediate

*Baeyer–Villiger reaction:* the oxidation of a ketone to an ester or lactone, usually by means of a peroxy acid

*Enone:* an unsaturated ketone, usually  $\alpha$ ,  $\beta$  relative to the carbonyl group

*Markovnikov orientation:* the 1,2-addition of an unsymmetrical electrophilic reagent to an alkene with attachment of the more positive moiety of the reagent (H in the original definition) to the less substituted carbon

*Michael addition:* conjugate addition; addition of a nucleophile to the  $\beta$ -position of a carbon–carbon double or triple bond that is conjugated to a carbonyl or other electron-withdrawing group

*Pummerer reaction:* the reaction of a sulfoxide or selenoxide with an acidic or electrophilic reagent, with cleavage of the S–O or Se–O bond and formation of an S- or Se-stabilized carbenium ion that rearranges or reacts further with nucleophiles

*S<sub>N</sub>2 mechanism:* a concerted, bimolecular nucleophilic substitution that occurs with inversion of configuration

*S<sub>RN</sub>1 mechanism:* a nucleophilic substitution that proceeds by a chain mechanism via radical anion intermediates

## Abbreviations

LDA = lithium diisopropylamide; MCPBA = *m*-chloroperoxybenzoic acid; DMF = *N,N*-dimethylformamide; HMPA = hexamethylphosphoric triamide.

## 1 INTRODUCTION

The element selenium was discovered by Berzelius in 1818, and reports of the first organoselenium compounds by Löwig, Wöhler, and others gradually appeared in the literature during the next 50 years. These compounds consisted mainly of simple aliphatic selenols (RSeH), selenides (RSeR), and diselenides (RSeSeR) that proved unpleasant to handle because of their highly malodorous nature. Difficulties in purification and the instability of certain derivatives also hampered early workers. Although the number and variety of known selenium compounds had grown dramatically by the 1950s, organoselenium chemistry remained a relatively arcane field of study until the 1970s. Around that time, the discovery of several useful new reactions and of a variety of novel structures with unusual properties began to attract more general interest in the discipline. This led to the appearance of several comprehensive texts on the chemical and biological properties of organoselenium compounds in the 1970s and 1980s.<sup>1–6</sup> Recent advances have also been driven by potential technological applications of, for example, selenium-containing organic conductors; by an increasing awareness of the biological importance of selenium compounds; and by the utility of organoselenium compounds in modern organic synthesis.<sup>7,8</sup> Today, a plethora of such species is known and key compounds are commercially available. Aryl-substituted derivatives and those containing selenium in higher oxidation states are generally less volatile and less offensive to handle than the original aliphatic compounds, and even the latter are now relatively easy to manipulate by modern techniques.

There are formal and behavioral resemblances between many types of organoselenium compounds and their sulfur and tellurium counterparts owing to their proximity in group 16 of the periodic table. For instance, selenols, selenides, diselenides, and selenoxides are in many ways analogous to thiols and tellurols, sulfides and tellurides, disulfides and ditellurides, and sulfoxides and telluroxides, respectively. However, despite formal similarities, there are also many differences between organoselenium, -sulfur, and -tellurium compounds with respect to their stabilities, properties, and reactions. The resemblance between organoselenium and oxygen compounds is considerably less pronounced because of the latter element's substantially higher electronegativity, lower polarizability, stronger bonds with carbon, and lack of available d orbitals for bonding.

## 2 SELENOLS AND SELENOLATES

Selenols ( $\text{RSeH}$ ) are relatively strong acids (e.g.  $\text{p}K_a = 5.9$  for  $\text{PhSeH}$ <sup>9</sup>) and so their conjugate bases, the selenolates ( $\text{RSe}^-$ ), are readily formed in alkaline solutions. They are most commonly prepared by the reaction of Grignard reagents or alkyl- or aryllithiums with elemental selenium, followed by acidification. Alternatively, selenols and selenolates can be obtained by the monoalkylation of hydrogen selenide or the  $\text{HSe}^-$  anion with alkyl halides or by the reduction of diselenides with reagents such as sodium borohydride, alkali metals, sodium or potassium hydride, sodium hydroxymethyl sulfoxylate (Rongalite), or hypophosphorous acid. The use of sodium borohydride results in the formation of a borane complex of the selenolate, which tends to suppress the reactivity of the selenolate. On the other hand, alkali metal selenolates in polar aprotic solvents such as DMF or HMPA display enhanced reactivity. The reduction or basic hydrolysis of selenocyanates ( $\text{RSeCN}$ ) also affords selenols and selenolates. These processes are shown in Scheme 1.

Although selenols and selenolates are weak bases, they are, nevertheless, powerful, soft nucleophiles<sup>10–12</sup> because of the high polarizability of the selenium atom. They therefore react readily with electrophilic compounds such as alkyl halides and tosylates to afford selenides, and with epoxides to give  $\beta$ -hydroxy selenides. These reactions occur via an  $\text{S}_{\text{N}}2$  mechanism with an inversion of configuration at carbon. Aryl halides also undergo substitution with selenolates by means of an  $\text{S}_{\text{RN}}1$  radical mechanism. Selenols are sufficiently acidic to protonate amines and form the corresponding ammonium selenolates. Attack by the highly nucleophilic selenolate anion upon an alkyl group of the ammonium cation of these species then affords the alkyl selenide and dealkylated amine.<sup>9</sup> Similar N-to-Se alkyl transfers have been carried out in the presence of ruthenium catalysts.<sup>13</sup> In contrast with most other nucleophiles, selenolates attack esters and lactones preferentially at the softer alkyl rather than the harder acyl carbon atom, with displacement of the corresponding carboxylate anion.<sup>10–12</sup> However, substitution at the acyl

Scheme 1

Scheme 2

center of methyl esters can be achieved with the selenoalane  $\text{Me}_2\text{AlSeMe}$ ,<sup>14</sup> to afford selenoesters. The cleavage of arylmethyl ethers and cyclopropanes with selenolates has also been reported. Selenols and selenolates perform Michael additions to enones and other activated alkenes and afford selenoacetals from aldehydes and ketones.<sup>10–12</sup> The selenoboranes  $\text{B}(\text{SePh})_3$  and  $\text{B}(\text{SeMe})_3$  are useful alternatives to selenols for this purpose.<sup>15</sup> These processes are illustrated in Scheme 2. Selenols and selenolates act as reducing agents toward a variety of organic functional groups, transforming vicinal dihalides into alkenes;  $\alpha$ -halo carbonyl compounds into dehalogenated products; nitro, nitroso, azo, azoxy, and hydrazo compounds into primary amines; imino compounds into secondary amines; and sulfoxides into sulfides.<sup>16,17</sup> Selenolates have also been immobilized on solid supports, and several synthetic applications have been reported.<sup>12</sup>

## 3 SELENIDES

Acyclic alkyl and aryl selenides ( $\text{RSeR}$ ) are generally stable and have a nonlinear structure. The  $\text{C-Se-C}$  bond angle of dimethyl selenide is  $96.3^\circ$  and the  $\text{C-Se}$  bond lengths are  $1.945 \text{ \AA}$ , as determined by microwave spectroscopy.<sup>18</sup> A variety of cyclic selenides of varying stability are also known.<sup>19</sup> For example, episelenides (**1**) are highly labile and extrude selenium spontaneously to generate alkenes. Selenetane (**2**) is isolable but polymerizes easily, while its 3,3-dimethyl derivative is more stable. Several 1,3-diselenetanes (**3**), as well as a variety of relatively stable larger rings, have been prepared. Transannular interactions between the selenium atoms of oxidized cyclic bis-selenides (e.g. **4**) have been studied<sup>20</sup> and several selenium analogs of crown ethers (e.g. **5**) have been reported.<sup>21</sup> Polymeric selenides such

as (6) and (7) are available from the reactions of  $\text{Na}_2\text{Se}$  with methylene bromide and *p*-dibromobenzene, respectively.

Alkyl selenides are most conveniently prepared by the dialkylation of  $\text{Na}_2\text{Se}$  or by the monoalkylation of selenolates. Common routes to aryl derivatives include the reaction of a selenolate with a diazonium salt, the  $\text{S}_{\text{RN}}1$  reactions described earlier, and the reaction of aryllithiums with aryl selenocyanates ( $\text{ArSeCN}$ ). A different approach employs the reaction of alcohols with aryl selenocyanates or *N*-(phenylseleno)phthalimide (see Section 6) in the presence of tri-*n*-butylphosphine.<sup>22</sup> Similar conditions can also be used to convert carboxylic acids to selenoesters (8). These reactions are illustrated in Scheme 3.

Selenides are also nucleophilic and produce isolable selenonium salts (9) when treated with alkyl halides. They are easily oxidized to selenoxides (10) and further to selenones (11) under more forcing conditions (see Section 4). Reduction of selenides to the corresponding hydrocarbons is most conveniently achieved with nickel boride,<sup>23</sup> or with tri-*n*-butyl- or triphenyltin hydride under radical conditions.<sup>24</sup> Other reagents for reductive deselenization include Raney nickel, lithium triethylborohydride, and lithium in ethylamine (Scheme 4). Benzylic selenides undergo radical extrusion reactions under thermal or photolytic conditions to produce

Scheme 3

Scheme 4

Scheme 5

coupled hydrocarbon products, including highly strained products such as benzocyclobutane and paracyclophanes (e.g. equation 1).<sup>25</sup> Selenium-stabilized carbanions (12) are usually formed by treating selenoacetals with *n*-butyllithium, which cleaves the C–Se bond in preference to deprotonating the  $\alpha$ -position. Alternatively, selenides containing  $\alpha$ -hydrogens can be deprotonated by strong bases such as lithium diisopropylamide (LDA), although the presence of an additional anion-stabilizing group, apart from the selenium atom, is generally required.<sup>26–29</sup> The anions can then be alkylated, acylated, or added to the carbonyl groups of aldehydes and ketones. These reactions are summarized in Scheme 5.

#### 4 SELENOXIDES AND SELENONES

Selenoxides (10) are easily prepared by the oxidation of selenides with numerous types of oxidants, including hydrogen

peroxide, peroxy acids, ozone, and sodium *m*-periodate. The reaction is easy to stop at this stage, and further oxidation to the selenone (**11**) requires strong oxidants such as peroxy acids and proceeds relatively slowly. This behavior contrasts with that of the analogous sulfur compounds, where the further oxidation of sulfoxides to sulfones is generally facile and often difficult to avoid.

Selenoxides derived from unsymmetrical selenides are chiral and stable toward pyramidal inversion at room or even higher temperatures.<sup>30</sup> They are produced enantioselectively by the use of chiral oxidants such as the Sharpless reagent<sup>31</sup> or camphor-derived oxaziridines<sup>32</sup> or diastereoselectively with achiral oxidants when one of the selenide substituents is itself chiral (see Section 9). Racemic selenoxides have been resolved by chromatography over chiral adsorbents.<sup>33</sup> Chiral selenoxides racemize readily in water,<sup>30</sup> particularly under acid-catalyzed conditions, presumably via the intermediacy of achiral selenoxide hydrates (equation 2).

The syn elimination of selenoxides<sup>34,35</sup> containing  $\beta$ -hydrogens is an exceptionally mild alkene-forming reaction that generally takes place at or below room temperature (equation 3). The introduction of an arylseleno group into an organic substrate, followed by its oxidation and elimination, is therefore one of the most valuable synthetic transformations effected with selenium chemistry. The reaction is stereospecific, and the transition state requires all five participating centers to assume a coplanar geometry, with the O atom and the abstracted H atom on the same side of the C–C bond. When diastereotopic  $\beta$ -hydrogens are present, abstraction of the one leading to the trans alkene is favored. The reaction often displays good regioselectivity in those cases where several sites containing  $\beta$ -hydrogens are available. Thus, the double bond is formed preferentially at conjugated positions, away from oxygen substituents to give allylic rather than vinylic products, and toward the less substituted position in the absence of other factors. Vinylic selenoxides containing cis hydrogens produce acetylenes as the major products along with smaller amounts of allenes, while those lacking cis hydrogens afford only the latter products (equation 4). Allylic selenoxides undergo rapid [2,3] sigmatropic rearrangements to the corresponding selenenate esters (**13**).<sup>35–37</sup> The latter then decompose readily to allylic alcohols by hydrolysis (equation 5). It is interesting to note that the reverse process is favored in the analogous sulfur rearrangements, where the equilibrium shifts toward the corresponding sulfoxides instead of the selenate esters. Under acidic conditions, or in the presence of electrophiles such as acetic anhydride,

selenoxides undergo Pummerer reactions (equation 6).

The chemistry of selenones<sup>38</sup> (**11**) has not been studied as extensively as that of selenoxides. However, it has been demonstrated that selenones function as good leaving groups, comparable to tosylates or halides.<sup>39,40</sup> For example, they are readily solvolyzed in methanol and produce rearranged products when  $\beta$ -substituents with high migratory aptitudes are present (equations 7 and 8). Vinylic selenones also act as Michael acceptors,<sup>41</sup> as in the first step of the process shown in equation (9).

## 5 DISELENIDES

Acyclic diselenides (RSeSeR), like disulfides and peroxides, are nonplanar and exhibit large dihedral angles. An X-ray

structure of diphenyl diselenide (PhSeSePh) revealed a dihedral angle of  $82^\circ$  and C–Se–Se angles of  $104.6^\circ$  and  $107.5^\circ$ , as well as Se–C and Se–Se bond lengths of 1.93 and 2.29 Å, respectively.<sup>42</sup> Bulky substituents increase the dihedral angle (e.g.  $112.1^\circ$  for *t*-Bu<sub>2</sub>CHSeSeCH-*t*-Bu<sub>2</sub>), lengthen the C–Se and Se–Se bonds, and result in bathochromic shifts in the UV spectrum,<sup>43</sup> while electronegative substituents shorten the diselenide bond. The preferred conformations of typical diselenides (roughly gauche with a dihedral angle of ca.  $80^\circ$ ) are chiral but interconvert rapidly by rotation about the diselenide bond. The barrier to rotation in benzyl phenyl diselenide (PhCH<sub>2</sub>SeSePh) has been measured to be  $6.3 \text{ kcal mol}^{-1}$  by dynamic NMR methods at low temperatures and is therefore  $1.4 \text{ kcal mol}^{-1}$  lower than that in the corresponding disulfide.<sup>44</sup> Simple cyclic diselenides such as (14) are known but tend to polymerize readily. A number of more complex cyclic diselenides have also been studied.<sup>45</sup> For example, the conformational properties of the paracyclophane diselenide (15) and its selenide counterpart were also investigated by dynamic NMR methods. The diselenide shows nonequivalent methylene protons at low temperatures and interconverts between syn conformers.<sup>46</sup> Theoretical, NMR, electrochemical, and photoelectron spectroscopic studies of cyclic diselenides and related 1,2-dichalcogenins have also been reported.<sup>47,48</sup>

Diselenides are generally prepared by the aerial oxidation of selenols or selenolates (see Section 2) or by the reaction of Li<sub>2</sub>Se<sub>2</sub>, Na<sub>2</sub>Se<sub>2</sub>, or other Se<sub>2</sub><sup>2-</sup> species with alkyl or aryl halides. In the latter case, elevated temperatures and DMF as the solvent are recommended. Aryl diselenides may also be obtained from the reaction of Se<sub>2</sub><sup>2-</sup> with diazonium salts (Scheme 6). Relatively few unsymmetrical diselenides have been reported. Triselenides are also known but have not been as widely studied.

As shown in Scheme 1, the reduction of diselenides generates selenols and selenolates, while their oxidation results in the formation of selenenic and seleninic acids and related compounds (see Section 7). Halogenation of diselenides with

Scheme 6

Scheme 7

sulfuryl chloride, chlorine, or bromine affords selenenyl halides (RSeX) or, with a second mole of halogenating reagent, the corresponding selenium trihalides (RSeX<sub>3</sub>). The reaction of diphenyl diselenide with iodine produces an adduct (16) that is probably a charge transfer complex instead of the selenenyl iodide.<sup>49</sup> This substance performs a number of typical reactions characteristic of a selenenyl halide, suggesting that free PhSeI may be present in solution. The more hindered bis(2,4,6-tri-*t*-butylphenyl) diselenide produced an authentic selenenyl iodide that was characterized by X-ray crystallography.<sup>50</sup> These processes are summarized in Scheme 7. The direct formation of selenenyl fluorides from the fluorination of diselenides has not yet been documented, but PhSeF, or an equivalent species, appears to be generated in situ from the sonication of PhSeBr or PhSeCl, in turn, obtained from halogenolysis of the corresponding diselenide, and AgF in a suitable solvent.<sup>51</sup> Similarly, the reaction of PhSeSePh with XeF<sub>2</sub> generates a species that behaves as the equivalent of PhSeF.<sup>52</sup> When photolyzed or pyrolyzed, diselenides undergo homolytic cleavage of the Se–Se bond, resulting in some interesting radical reactions,<sup>53</sup> such as radical 1,2-additions to acetylenes.<sup>54,55</sup> A palladium-catalyzed 1,2-addition of diselenides to acetylenes has also been reported, which can be performed in the presence of CO to afford (*Z*)-1,3-bis(arylseleno)-2-alken-1-ones.<sup>56</sup> Diazo compounds insert into the Se–Se bond and into a variety of selenium–heteroatom bonds.<sup>57</sup> Some examples of these processes are shown in Scheme 8. Benzylic diselenides extrude selenium under either photolytic or pyrolytic conditions to produce selenides (equation 10),<sup>53</sup> which in turn afford hydrocarbons from

Scheme 8

further extrusion reactions, as indicated earlier.

## 6 SELENENYL HALIDES AND PSEUDOHALIDES

Selenenyl halides are relatively stable, though moisture sensitive, compounds that are generally prepared by the reactions shown in Scheme 7 and behave as electrophilic selenium species.<sup>57–59</sup> They react with ketones and aldehydes via their enols or enolates to afford  $\alpha$ -seleno derivatives (e.g. **(17)** in equation 11). Similar  $\alpha$ -selenenylations of  $\beta$ -dicarbonyl compounds, esters, and lactones can be performed, although the latter two types of compounds require prior formation of their enolates. Moreover, the  $\alpha$ -selenenylation of anions stabilized by nitrile, nitro, sulfone, or various types of phosphorus substituents has also been reported (equation 12). In many such cases, the selenenylation step is followed by oxidation to the selenoxide and spontaneous syn elimination to provide a convenient method for the preparation of the corresponding  $\alpha,\beta$ -unsaturated compound (e.g. **(18)** in equation 11). Enones react with benzeneselenenyl chloride (PhSeCl) and pyridine to afford  $\alpha$ -phenylselenoenones (equation 13).

Selenenyl chlorides add to alkenes, often via an  $\text{Ad}_\text{E}2$  mechanism involving a bridged seleniranium ion intermediate<sup>60</sup> **(19)** (equation 14). These reactions are therefore highly stereospecific, resulting in anti addition. The regiochemistry of the process can be under either kinetic or thermodynamic control. In some cases, initial anti-Markovnikov products were observed at low temperature and Markovnikov adducts dominated after further equilibration. Analogous electrophilic additions to acetylenes and allenes (Scheme 9) have also been reported. When selenenyl halides react with alkenes in the presence of other nucleophiles such

Scheme 9

as water, alcohols, nitriles, or azide or nitrite anions, a 1,2-addition of the selenium residue and the nucleophile to the  $\text{C}=\text{C}$  double bond is often observed (Scheme 9). When a nucleophilic group is present elsewhere in the alkenic substrate, the reaction is intramolecular, resulting in cyclization (e.g. equation 15).<sup>58,59,61,62</sup>

Other species of general structure  $\text{RSeX}$ , where X = a nonhalide leaving group, are also known and often show similar behavior to that of the selenenyl halides.<sup>57–59</sup> For example, benzeneselenenyl acetate **(20)**, trifluoroacetate **(21)**, and tosylate **(22)** can be generated in situ from the reactions of the selenenyl halides with silver acetate, trifluoroacetate, or tosylate, respectively (Scheme 10). The former two electrophiles react with enol acetates to produce  $\alpha$ -seleno ketones and with alkenes and acetylenes to give 1,2-addition products, while the latter adds similarly to acetylenes. Examples are shown in equations (16) to (18).

Scheme 10

Selenenamides (**23**) are obtained by the substitution of selenenyl halides with amines<sup>63</sup> or by the metathesis of the former compounds with *N*-silylamines.<sup>64</sup> *N*-(Phenylseleno)phthalimide (**24**) is similarly obtained using potassium phthalimide (Scheme 10).<sup>65</sup> These compounds can be isolated but are prone to hydrolyze when exposed to moisture. Selenenamides react with aldehydes or  $\beta$ -dicarbonyl compounds to afford  $\alpha$ -seleno derivatives (as in the process shown in equation 11), and add to activated double and triple bonds, as in the example in equation (19). The imide (**24**) is a useful alternative to PhSeCl in various selenenylation reactions, and to ArSeCN in the conversion of alcohols and carboxylic acids to selenides and selenoesters (**8**), as shown in Scheme 3.

The preparation of selenocyanates<sup>66</sup> such as (**25**) can be achieved by the methods shown in Scheme 10, although a useful alternative employs the reaction of potassium

selenocyanate (KSeCN) with alkyl halides or arenediazonium salts (equation 20).

Selenocyanates produce selenols or diselenides upon either reduction (e.g. with sodium borohydride) or hydrolysis (see Scheme 1). They undergo displacement of the cyanide ion by various nucleophiles and add to alkenes in a manner similar to selenenyl halides (see equation 14), except that catalysis with Lewis acids is required in the case of unactivated alkenes. The selenocyanates are also popular reagents for the preparation of selenides from alcohols, and (**8**) from carboxylic acids, as indicated in Scheme 3.

The selenosulfonates (**26**) comprise another class of selenenyl pseudohalides.<sup>67</sup> They are stable, crystalline compounds available from the reaction of selenenyl halides with sulfinate salts (Scheme 10) or more conveniently from the oxidation of either sulfonylhydrazides (ArSO<sub>2</sub>NHNH<sub>2</sub>) or sulfinic acids (ArSO<sub>2</sub>H) with benzeneseleninic acid (**27**) (equations 21 and 22). Selenosulfonates add to alkenes via an electrophilic mechanism catalyzed by boron trifluoride etherate, or via a radical mechanism initiated thermally or photolytically. The two reaction modes produce complementary regioselectivity, but only the electrophilic processes are stereospecific (anti). Similar radical additions to acetylenes and allenes have been reported, with the regio- and stereochemistry as shown in Scheme 11. When these selenosulfonation reactions are used in conjunction with subsequent selenoxide eliminations or [2,3] sigmatropic rearrangements, they provide access to a variety of unsaturated sulfone products.

Several types of electrophilic selenium species have been immobilized on solid supports, for more convenient application to organic synthesis. These include selenenyl halides,<sup>68–71</sup> selenocyanates,<sup>72</sup> and selenosulfonates.<sup>73</sup>

## 7 SELENENIC AND SELENINIC ACIDS AND DERIVATIVES

The partial oxidation of diselenides with appropriate oxidants such as hydrogen peroxide initially generates the corresponding selenenic acids (**29**) or anhydrides (**28**). Further oxidation leads to the corresponding seleninic acids (**31**) or

Scheme 11

Scheme 12

anhydrides (30), as shown in Scheme 12. Though the seleninic compounds (30) and (31) are usually stable and isolable, their selenenic counterparts (28) and (29) are generally not and disproportionate to mixtures of the initial diselenide and the seleninic acid or anhydride. The disproportionation probably involves intermediates (32) and (33) (Scheme 12). Several early reports of isolable selenenic acids proved erroneous, although (34) has been characterized in solution.<sup>74</sup> More recently, selenenic acids (35)<sup>75</sup> and (36)<sup>76</sup> were isolated and characterized by X-ray crystallography. A few selenenic anhydrides have been prepared (e.g. 37 and 38, which are stabilized by the ortho substituent).<sup>77,78</sup> The unstable selenolseleninate (39) was observed<sup>79</sup> when the corresponding cyclic diselenide was oxidized with 1 equiv of MCPBA (*m*-chloroperbenzoic acid) at low temperatures, and the similar oxidation of the 1,8-*peri*-diselenide of naphthalene produced a mixture of selenolseleninate (40) and selenenic anhydride (41).<sup>80</sup> The X-ray structure of an isolable selenolseleninate, structurally related to (36), has

been reported.<sup>76</sup> Selenenic acids can also be generated in situ by the hydrolysis of selenenyl halides or other derivatives of the general structure  $\text{RSeX}$ , where X is a leaving group, and by the reduction of seleninic acids or anhydrides. The comproportionation of the latter with diselenides (i.e. the reverse of the disproportionation process in Scheme 12) also produces low equilibrium concentrations of (28) or (29). The continuous removal of (28) or (29) by their reaction with an appropriate substrate can, however, drive the reaction to completion.

When selenenic acids are generated in the presence of alkenes, addition reactions similar to those of selenenyl halides occur. Oxidation and syn elimination of the adducts (42) provide a convenient synthesis of allylic alcohols (equation 23).<sup>57-59</sup>

Benzeneseleninic acid (27) and the corresponding anhydride (43) are widely employed as oxidants in organic synthesis.<sup>81,82</sup> The acid is conveniently prepared by the oxidation of diphenyl diselenide (PhSeSePh) with nitric acid, followed by neutralization of the resulting hydronitrate complex (PhSeO<sub>2</sub>H·HNO<sub>3</sub>) with a base. The anhydride is obtained by heating the acid in vacuo at ca. 120 to 130 °C. These reagents oxidize phenols to quinones, and primary and secondary alcohols to aldehydes and ketones, respectively. Amines afford imines and the corresponding ketones by subsequent hydrolysis, while hydrazine and its 1,2- and 1,1-disubstituted derivatives produce diimide,

Scheme 13

azo compounds, and tetrazenes, respectively. *N*-Acyl- and *N*-sulfonylhydrazines give selenoesters (8) and selenosulfonates (26) (see equation 21). These reagents are also useful in regenerating ketones from their hydrazones, oximes, semicarbazones, and dithioacetals. Thiones and other thiocarbonyl compounds are converted into the analogous ketones and other corresponding carbonyl compounds, and sulfinic acids afford (26) via equation (22). These processes are illustrated in Scheme 13. They augment the uses of inorganic selenium oxidants such as selenium dioxide (see *Selenium: Inorganic Chemistry*).

The dehydrogenation of steroidal and other ketones can be accomplished with (43) at elevated temperatures.<sup>81,82</sup> Similar reactions with lactones and lactams have also been reported. Other interesting oxidations include the angular hydroxylation of ketones and the oxidation of benzylic hydrocarbons, as shown in Scheme 14. In some cases, the selenium reagent may be employed catalytically in the presence of a less expensive cooxidant that reoxidizes Se<sup>II</sup> by-products back to the required Se<sup>IV</sup> oxidation state.

Seleninic acids can also be employed in epoxidation and Baeyer–Villiger reactions<sup>81,82</sup> when used in conjunction with

Scheme 14

hydrogen peroxide (Scheme 15). Intermediate peroxyseleninic acids (44) are likely intermediates in these processes.

Scheme 15

Selenonic acids (45) have been little studied but can be produced by the further oxidation of seleninic acids with potassium permanganate.

## 8 SELENOCARBONYL COMPOUNDS

The relatively poor 2p–4p  $\pi$ -overlap of carbon–selenium double bonds makes selenocarbonyl groups less stable than the corresponding thiocarbonyl and carbonyl analogs. Until the mid-1970s, only those selenocarbonyl compounds where the bond order of the  $\text{C}=\text{Se}$  bond was lowered by coordination or resonance were known. However, the isolation of two deep blue, thermally stable selones (46) and (47) proved that such

Scheme 16

species could exist without electronic stabilization, provided that they were sterically protected.<sup>83</sup> Scheme 16 shows several methods for preparing selenones and related selenocarbonyl compounds.<sup>83–86</sup> Perhaps their most notable chemical property involves their cycloaddition with diazo compounds to afford cycloadducts (48), which undergo twofold extrusion of N<sub>2</sub> and Se to afford alkenes (equation 24).<sup>83</sup> This method has been employed to produce some of the most hindered alkenes known to date.<sup>83–86</sup> Unlike ketones, selenones are attacked by nucleophiles such as phenyllithium at the Se and not the C atom, producing selenium-stabilized carbanion intermediates. They act as spin-traps for radicals, which also attack at the selenium atom. Selenones are easily reduced to diselenides by hydrogen selenide, by typical reducing agents such as sodium borohydride, or by photolysis. Less stable selenones and selenoaldehydes have been trapped by cycloaddition with cyclopentadiene or other 1,3-dienes,<sup>87</sup> or isolated as the dimeric 1,3-diselenetanes (e.g. (3; R = Ph) from Ph<sub>2</sub>C=Se)<sup>88</sup> or as higher oligomers or polymers. Selenoesters and selenoamides tend to be inherently more stable than selenones because of resonance and can be prepared as shown in Scheme 16. A variety of other selenocarbonyl compounds, including carbon diselenide, carbon oxyselenide, selenoureas, selenocarbonates, selenoketenes, and others have also been reported.<sup>84–86</sup>

## 9 CHIRAL ORGANOSELENIUM COMPOUNDS

As indicated in Section 4, selenoxides bearing two different substituents are intrinsically chiral (i.e. the selenium atom itself is a stereocenter), although their resolution can be challenging. Certain other types of organoselenium compounds, such as selenonium salts (9) containing three different substituents, are also chiral and can sometimes be resolved into their respective enantiomers. Moreover, there is growing interest in organoselenium compounds that contain chiral auxiliary groups attached to the selenium atom. In this case, the selenium atom is not the stereocenter, which is instead present in the auxiliary.

A number of useful enantioselective syntheses can be performed by attaching a chiral auxiliary group to the selenium atom of an appropriate reagent.<sup>89,90</sup> Examples of such chiral auxiliaries include (49–53). Most of the asymmetric selenium reactions reported to date have involved inter- or intramolecular electrophilic additions to alkenes (i.e. enantioselective variations of processes such as shown in equations (23) and (15), respectively) but others include the desymmetrization of epoxides by ring-opening with chiral selenolates, asymmetric selenoxide eliminations to afford chiral allenes or cyclohexenes, and the enantioselective formation of allylic alcohols by [2,3]sigmatropic rearrangement of allylic selenoxides or related species.

## 10 ORGANIC CONDUCTORS

A plethora of selenium-containing heterocycles are known to act as the donor component for donor–acceptor complexes that have properties as electrical conductors.<sup>91–93</sup> Two examples that have provoked widespread interest are tetraselenafulvalene (**54**) and tetraselenotetracene (**55**). A variety of selenium-containing polymers such as (**7**) are also of interest in this regard.

## 11 BIOLOGICALLY IMPORTANT ORGANOSELENIUM COMPOUNDS

Organoselenium compounds play several important biological roles.<sup>2,94–98</sup> They are generally toxic and so must be handled with appropriate care. Selenium intoxication symptoms in animals include ‘alkali disease’ and ‘blind staggers’, symptoms of which have been known for many years. On the other hand, selenium is also an essential trace element and its deficiency in the diet is severely detrimental to both animal and human health and has been implicated in white muscle disease and cardiac myopathy. Moreover, selenium compounds have been claimed to act as carcinogens, while other reports suggest that in appropriate doses they are anticarcinogens. Selenium compounds, in some cases acting synergistically with vitamin E, have apparent roles as anti-inflammatory agents, in maintaining the normal functioning of the immune system, and possibly in retarding the aging process. Much of the biological activity of selenium is associated with its incorporation into selenocysteine residues in the enzyme glutathione peroxidase (see *Selenium Proteins Containing Selenocysteine*), which functions as an antioxidant. This protein catalyzes the reduction of harmful peroxides by glutathione. The peroxides are produced during the course of normal oxidative metabolism and result in damage to biologically important molecules, as well as to cell membranes. A variety of inflammatory conditions and other disease states are related to the undesired physiological effects of peroxides and the free radicals that are produced by them. A number of other selenium-containing proteins are known, along with the semisynthetic enzyme selenosubtilisin.<sup>99</sup> Several small-molecule synthetic compounds designed to mimic the antioxidant effects of glutathione peroxidase have been reported. These include ebselen (**56**),<sup>100</sup> a compound which has undergone clinical

trials, as well as more recent compounds<sup>98,101</sup> (e.g. **57–61**), some displaying improved catalytic activity. Organoselenium compounds with antibacterial, antiviral, antifungal, antiparasitic, and antiradiation properties have also been reported, as well as selenium analogs of a variety of carbohydrates and nucleosides.

## 1 INTRODUCTION

As a member of group 6 of the periodic table of elements, selenium shares many chemical properties with its neighboring homolog, sulfur (*see Selenium: Inorganic Chemistry; Selenium: Organoselenium Chemistry*). Both elements occur in the same oxidation states  $-2$ ,  $0$ ,  $+2$ ,  $+4$ , and  $+6$  and they both enter biological macromolecules (protein; tRNA) in the  $-2$  state. However, selenium also differs from sulfur in a number of important properties. The most significant one is that selenol is a more powerful nucleophile than thiol. Since the  $-\text{SeH}$  group of selenocysteine in proteins exhibits a  $pK$  of about  $5.2$ , it is mostly dissociated at the physiological pH, whereas the  $-\text{SH}$  group with an average  $pK$  of  $8.6$  is predominantly protonated. Therefore, as has been shown for several enzymes, the incorporation of a chemically more reactive selenol group into the active center instead of a thiol confers a dramatic catalytic advantage. This review deals with enzymes from prokaryotes and eukaryotes, which contain a covalent selenocysteine residue, and also describes the present knowledge of its biosynthesis and mode of incorporation. The topic has been covered in several reviews concentrating on the biochemical, the nutritional and physiological, the molecular biological, and the biomedical aspects.<sup>1–6</sup> A comprehensive treatise has been compiled recently by Hatfield.<sup>7</sup>

## 2 PROKARYOTIC SELENOPROTEINS

### 2.1 Formate Dehydrogenases

Selenocysteine-containing formate dehydrogenases occur widely in nature. Operationally, they can be differentiated

into two groups: enzymes that unidirectionally cleave formate into  $\text{CO}_2$  and reducing equivalents, and enzymes that can act bidirectionally by interconverting formate and  $\text{CO}_2$  plus reducing equivalents.

#### 2.1.1 Unidirectionally Acting Formate Dehydrogenases

Unidirectionally operating formate dehydrogenases couple formate oxidation to the reduction of endogenously formed or exogenously added electron acceptors. Well-studied examples are the three formate dehydrogenase isoenzymes from *Escherichia coli* or the  $\text{F}_{420}$ -reducing formate dehydrogenases from archaea.

Under fermentative conditions, *E. coli* synthesizes the so-called formate hydrogenylase complex, which consists of formate dehydrogenase H, several electron carriers, and hydrogenase 3. The formate dehydrogenase H component consists of an 80-kDa selenopolypeptide encoded by the *fdhF* gene and catalyzes the reaction<sup>1</sup>

The *fdhF* gene product has been purified and subjected to a detailed biochemical and structural analysis.<sup>8,9</sup> It contains an  $\text{Fe}_4\text{S}_4$  cluster, two molybdopterin–guanine dinucleotide cofactors and a selenocysteine in the active site, and it displays ping-pong bi-bi kinetics for the substrate formate and the artificial one-electron acceptor benzylviologen. The pH profile of inactivation by alkylation follows exactly the dissociation state of the selenol and indicates that selenocysteine is participating in the binding of formate.<sup>8,9</sup>

During anaerobic growth in the presence of nitrate, *E. coli* synthesizes formate dehydrogenase N, which couples formate oxidation to nitrate reduction:

The enzyme has been first purified by Enoch and Lester<sup>10</sup> and recently shown by X-ray analysis to be a 510-kDa membrane-bound complex of  $(\alpha\beta\gamma)_3$  structure.<sup>11</sup> It channels the electrons withdrawn from formate by the  $\alpha$ -subunit, which is a selenopolypeptide of 110-kDa molecular mass<sup>12</sup> via 11 redox centers consisting of molybdopterin–guanine dinucleotides and five  $\text{Fe}_4\text{S}_4$  centers in a single unbranched chain to two heme b groups in the  $\gamma$ -subunit, which also contains a quinone binding site. The formate-binding site is located at the periplasmic side, the quinone reduction site at the opposite side of the cytoplasmic membrane.

Formate dehydrogenase O is present in *E. coli* cells grown aerobically or anaerobically in the presence of nitrate.<sup>13</sup> It is the least well-studied of the three isoenzymes, although it is this system for which a biological role of the element selenium was first demonstrated.<sup>14</sup> Formate dehydrogenase O appears to act as an oxidoreductase coupling formate oxidation with quinone reduction, but a detailed analysis of its structure and redox partners has not yet been carried out.

Depending on the selenium status of the growth medium, *Methanococcus vannielii* synthesizes either one of the two formate dehydrogenases.<sup>15</sup> In the absence of selenium, cells contain a formate dehydrogenase activity that is associated with a 105-kDa polypeptide, which carries a molybdenum cofactor and Fe/S center(s) (1 Mo and 10 FeS), but lacks selenium. When selenite is added to the medium, a 100-kDa selenocysteine-containing polypeptide is formed, which is associated with the 105-kDa polypeptide carrying the Mo–FeS centers. This enzyme complex exhibits a higher catalytic activity than the 105-kDa species alone.<sup>15</sup> Both catalytic species couple formate oxidation to the reduction of the 8-hydroxy-5-deazaflavin cofactor (F<sub>420</sub>) present in methanogenic bacteria.

### 2.1.2 Bidirectionally Acting Formate Dehydrogenases

Acetogenic bacteria such as *Clostridium (Cl.) thermoaceticum* or *Cl. formicoaceticum* catalyze an NADPH<sub>2</sub>-driven CO<sub>2</sub> reduction to formate, which is further reduced via the tetrahydrofolate pathway to the –CH<sub>3</sub> oxidation state, as the methyl is finally incorporated into acetic acid. This ‘anabolic’ formate dehydrogenase has long been known to depend on the presence of Se in the medium for its formation.<sup>16</sup> The enzyme is an α<sub>2</sub>β<sub>2</sub> heterooligomer of 340 kDa; the complex contains two selenocysteine residues, two moles of a tungsten cofactor, and Fe/S centers.<sup>17</sup>

## 2.2 Hydrogenases

Hydrogenases that catalyze the reversible oxidation of molecular hydrogen into protons and electrons can be classified based on their metal cofactor content into ‘Fe-only’ hydrogenases and [NiFe] hydrogenases, which also include [NiFeSe] hydrogenases.<sup>18</sup> The amino acid position occupied by the selenocysteine residue in [NiFeSe] hydrogenases is taken by a cysteine residue in [NiFe] hydrogenases. [NiFeSe] hydrogenases are formed by methanogenic bacteria, such as *Methanococcus (M.) vannielii*,<sup>19</sup> *M. voltae*,<sup>20</sup> *M. jannaschii*,<sup>21</sup> and *M. maripaludis*,<sup>3</sup> and by several sulfate-reducing bacteria such as *Desulfomicrobium (D.) baculatum*.<sup>18</sup> The [NiFeSe] hydrogenase of *D. baculatum* exhibits the classical αβ heterodimeric structure of Ni-containing hydrogenases<sup>18</sup> with the large (α) subunit displaying a molecular mass of 62 kDa and the small (β) one a mass of 32 kDa. The large subunit is the selenocysteine-containing polypeptide and also carries the Ni in a 1:1 ratio to Se. Fe/S centers are present in both subunits.<sup>18</sup> EPR spectroscopy of the <sup>77</sup>Se-enriched enzyme and Ni and Se EXAFS studies revealed a direct coordination of the nickel atom to selenium,<sup>22</sup> which indicates that one of the four thiolate ligands of the metal center in [NiFe] enzymes is replaced by a selenocysteyl moiety in [NiFeSe] enzymes.

## 2.3 Glycine Reductase

A number of obligate anaerobic bacteria can ferment amino acids or purine bases by using glycine as the electron acceptor. The key enzyme for this fermentation pathway is glycine reductase; it is unique since it is the only reduction reaction known, which is coupled with energy generation via a substrate-level phosphorylation.<sup>23</sup> The overall balance of the fermentation of an alanine/glycine pair by Stickland organisms like *Cl. sticklandii* or *Eubacterium (E.) acidaminophilum* is given by equation (3), and that of the purine degradation intermediate formiminoglycine by *Cl. purinolyticum* or *Cl. cylindrosporium* by equation (4).

Three proteins, termed P<sub>A</sub>, P<sub>B</sub>, and P<sub>C</sub>, contribute to the formation of the membrane-bound glycine reductase complex.<sup>1,2</sup> P<sub>A</sub> is a 12.5-kDa acidic glycoprotein containing a single selenocysteine (U) residue in a sequence context (CxxU) also present in thioredoxins. P<sub>A</sub> actually was the first protein for which the organoselenium compound selenocysteine was identified.<sup>24</sup> Protein P<sub>B</sub> also contains a single selenocysteine residue<sup>25</sup> and appears to function in the activation of the specific substrate. Finally, P<sub>C</sub> is an α<sub>4</sub>β<sub>4</sub> oligomer where β (48 kDa) carries an acetyl-accepting SH group and α (57 kDa) serves as a membrane anchor for the total glycine reductase complex.

The reaction cycle (Figure 1) initiates by the formation of a Schiff base between glycine and a pyruvoyl group carried by protein P<sub>B</sub>. The Schiff base is then attacked by the selenol of protein P<sub>A</sub>, resulting in formation of a Se–carboxymethyl intermediate. The next step has not yet been clearly resolved, but on completion, results in the transfer of an acetyl group to the thiol of the β-subunit of protein P<sub>C</sub> to yield an acetyl-thioester of P<sub>C</sub> and leaving protein P<sub>A</sub> in an intramolecular selenadisulfide form. The acetyl-thioester is then cleaved phosphoroclastically with acetylphosphate being released,<sup>23</sup> and the oxidized protein P<sub>A</sub> can be reduced involving a redox chain from NADH<sub>2</sub>, thioredoxin reductase, and thioredoxin.<sup>26</sup>

## 2.4 Selenoenzymes Involved in Methanogenesis

The analysis of the genome of methanogenic bacteria, in particular, of *M. jannaschii*, disclosed the existence of a number of selenoenzymes involved in the reduction of CO<sub>2</sub> into CH<sub>4</sub>.<sup>3,21</sup> Apart from the two classes of hydrogenases (F<sub>420</sub>-reducing and F<sub>420</sub>-nonreducing hydrogenases) and the formate dehydrogenase mentioned above, these are formyl-methanofuran dehydrogenase and heterodisulfide reductase. Since these enzymes are essential for energy generation, the

organism displays an obligate growth requirement for selenium. Intriguingly, growth of the closely related methanogen *M. maripaludis* on  $H_2$  and  $CO_2$  is independent of the availability of selenium since it possesses a 'backup' system of homologs, which contain a cysteine residue in the position of selenocysteine.<sup>27</sup> An exception is formate dehydrogenase for which no such sulfur homolog exists and consequently growth at the expense of formate requires a supply of selenium. When *M. maripaludis* is cultivated under selenium-adequate conditions, the sulfur enzymes are not synthesized; therefore, selenium or a follow-up product in its metabolism must exert a repressive effect on their formation.<sup>27</sup>

**Figure 1** Reactions involved in the glycine reduction pathway by *Clostridia*.  $P_A$ ,  $P_B$ , and  $P_C$  denote the components of the glycine reduction complex where  $P_B$  is specific for the substrate (e.g. glycine, betaine, sarcosine). The reduction of oxidized protein  $P_A$  occurs via a redox chain involving thioredoxin reductase (TR) and thioredoxin (TRX). The involvement of ketene as an intermediate has not yet been proven

### 3 EUKARYAL SELENOPROTEINS

A recent computational screen of the human genome resulted in the identification of 25 open reading frames as coding for putative selenoproteins.<sup>28</sup> Because of space limitation, this review concentrates only on the discussion of those proteins for which a biochemical function or an important physiological role had been attributed.

#### 3.1 Glutathione Peroxidases

Four different classes of selenium-dependent glutathione peroxidases are known at present: cytoplasmic glutathione peroxidases, plasma glutathione peroxidases, gastrointestinal glutathione peroxidase, and phospholipid hydroperoxide glutathione peroxidases. They all catalyze the reduction of hydroperoxide and organic hydroperoxides by reduced glutathione:

Cytoplasmic glutathione peroxidase is by far the most thoroughly studied species and has been extensively reviewed.<sup>29</sup> It was also the first selenoenzyme to be purified and demonstrated to contain covalently bound selenium.<sup>30</sup> The enzyme is present in the tissues of all mammalia and birds studied. Depending on the species, the molecular mass of the enzyme ranges between 76 and 94 kDa. It is composed of four identical constituent subunits that contain a single selenocysteine residue each.

A detailed kinetic analysis and the modeling of enzyme-substrate complexes with the aid of the 3D structure<sup>31</sup> have led to the suggestion of the reaction mechanism detailed in Figure 2.

According to this model, the dissociated selenol of the selenocysteine in the active center reacts with the

**Figure 2** Reaction cycle catalyzed by glutathione peroxidase. GSH and GSSG denote reduced and oxidized glutathione, respectively

hydroperoxide (ROOH), which is reduced to the alcohol state. The selenolate, however, is oxidized to selenic acid, which can now react with reduced glutathione to form a mixed protein–glutathione–selenadisulfide. Experimentally, such an intermediate has been demonstrated to exist. In a consecutive and final step, the mixed selenadisulfide is reduced by a second glutathione molecule, regenerating the protein with a free selenol and producing oxidized glutathione. The efficiency of this regeneration depends on the glutathione concentration, a high concentration in the mM range being crucial, since the rate of this reaction is about two orders of magnitude lower than that of the hydroperoxide with the selenolate. According to the suggested model, selenium changes its oxidation state during the reaction cycle.

A glutathione peroxidase, distinct from the cellular enzyme species, has been purified from human plasma.<sup>32</sup> Its molecular mass was determined to be approximately 100 kDa and it was shown to be a tetrameric protein of identical subunits. Like the cytoplasmic form, it contains four atoms of selenium per mole of protein. In contrast to its cellular counterpart, however, the plasma protein is glycosylated. It catalyzes the reduction of both  $H_2O_2$  and organic hydroperoxides, its affinity for glutathione being an order of magnitude lower than that of the cytoplasmic enzyme. Since the concentration of glutathione in plasma is far below the affinity of the enzyme, it is questionable whether glutathione is the natural substrate. Whereas the cellular enzymes from different species or tissues generally share sequence similarities between 80–95%, the plasma enzyme is evolutionarily more distant.

Ursini and collaborators purified a glutathione peroxidase from pig heart and pig liver that reduced phospholipid hydroperoxides with glutathione as a reductant, especially in the presence of a detergent.<sup>33</sup> Cellular and plasma glutathione peroxidases do not attack lipid hydroperoxides *in vitro* even in the presence of detergents. The enzyme is a 21-kDa monomer and contains a single selenocysteine residue.<sup>34</sup> The enzyme, termed ‘phospholipid hydroperoxide glutathione peroxidase’ (PHGPx), is believed to be the major determinant that protects membrane phospholipids from oxidative damage. Apart from this protective effect, PHGPx is involved in the modulation of inflammatory processes by regulating the biosynthesis of leukotrienes and prostaglandins, and may downregulate cytokine-induced transcription activation.<sup>35</sup>

PHGPx also fulfills a fascinating structural role during spermatogenesis. It is an active peroxidase in the spermatids and develops into a major structural protein of the mitochondrial capsule of the spermatozoa. The formation of the capsule involves the  $H_2O_2$ -stimulated formation of keratin-like protein polymers linked via intramolecular and also intermolecular selenadisulfides with thiols of other proteins. It appears that PHGPx, which is present in extraordinarily high levels and also in different forms in the testes, is responsible for the long-known selenium dependence of male fertility.<sup>36</sup>

### 3.2 Tetraiodothyronine Deiodinases

3,3',5,5'-Tetraiodothyronine ( $T_4$ ; thyroxine) is synthesized in the thyroid gland and converted into 3,3',5-triiodothyronine ( $T_3$ ) and 3,3',5'-triiodothyronine (reverse  $T_3$ ,  $rT_3$ ) by tetraiodothyronine deiodinases in nonendocrine organs.<sup>37</sup> The type I deiodinase is formed in the liver and the kidney, and catalyzes the formation of  $T_3$  and  $rT_3$ ; this class of deiodinase is responsible for producing the major part of  $T_3$  present in the plasma. The type II enzyme is present in other tissues such as the central nervous system and is thought to contribute most of the  $rT_3$  of the plasma. A third deiodinase (type III) is responsible for converting  $T_4$  into hormonally inactive  $T_3$  metabolites. All three deiodinases are selenoenzymes<sup>37–39</sup> with a single selenocysteine residue each. They are encoded by different genes and they control the tissue-specific availability of the endocrine hormone  $T_3$ .<sup>40</sup>

The reaction cycle depicted in Figure 3 proposes that the enzyme with a free selenolate reacts with  $T_4$  to produce  $T_3$  and an enzyme–iodide intermediate. The selenolate is regenerated and the iodide released by reaction with reduced glutathione. The model also explains the inhibitory actions of gold thioglucose, which reacts with the selenolate, and of propylthiouracil, which releases the iodide from the enzyme–iodide intermediate and forms an enzyme–propylthiouracil–selenadisulfide.

### 3.3 Thioredoxin Reductase

In 1996, Tamura and Stadtman showed that thioredoxin reductase from mammalia – in contrast to the bacterial homologs – is a selenoprotein, and that selenocysteine is the penultimate C-terminal amino acid residue.<sup>41</sup> Selenium-containing isoenzymes, which are tissue specific, have later on been characterized biochemically, or the existence of such isoforms was suggested by *in-silico* methods.<sup>4,28,42</sup> The substrate of thioredoxin reductase is thioredoxin, which is the key regulator of the redox status within cells. Thioredoxin catalyzes thiol-disulfide exchange reactions in proteins and peptides; it is involved as redox mediator in the

**Figure 3** Reaction cycle catalyzed by the type I tetraiodothyronine deiodinase.  $T_4$  = 3,3',5,5'-tetraiodothyronine;  $T_3$  = 3,3',5-triiodothyronine;  $Au^+$  = gold thioglucose; PU-SH = propylthiouracil

reaction of ribonucleotide reductase and in the activation of transcription factors and nuclear receptors. Thus, thioredoxin reductase regulates a multitude of metabolic processes and is involved in regulatory cascades within the eukaryal cell.<sup>43</sup> The enzyme is a homodimer with a head-to-tail orientation of the two subunits that form an intersubunit catalytic center.<sup>44</sup> The required reducing equivalents are derived from NADPH and transferred via FAD to a central CysXXXXCys motif of the protein, which in its oxidized form interacts with the selenocysteine of the opposite subunit via a selenadisulfide bond with the concomitant transfer of the reducing equivalents to the oxidized thioredoxin<sup>45</sup> (Figure 4). Both thioredoxin and thioredoxin reductase are essential proteins; the knock out of their genes causes embryonic lethality.

### 3.4 Methionine Sulfoxide Reductase

Mammalia contain two methionine sulfoxide reductases, forms A and B. Methionine sulfoxide reductase B is a selenoprotein, which reduces the R form of free or protein-bound methionine sulfoxides to methionine with thioredoxin as the reductant.<sup>46</sup> Together with isoform A (which does not contain selenium), the enzyme can repair oxidatively damaged protein and thus contributes to the antioxidant system of the cell.<sup>47</sup>

### 3.5 Plasma Selenoprotein P

Plasma from mammalia contains a selenoprotein that carries more than 50% of the selenium present. In rat, about 8% of the total selenium content is associated with this protein, selenoprotein P.<sup>48</sup> A change in the selenium status of the rat leads to a rapid change of the selenium level attached to selenoprotein P, preferential to changes of other selenoproteins such as plasma glutathione peroxidase.<sup>48</sup>

Selenoprotein P is a glycoprotein; the sequence of the protein moiety within it, having a molecular mass of about 41 kDa, was deduced from the nucleotide sequence of the rat gene.<sup>49</sup> It is unique since, dependent on the organism, it contains more than a dozen selenocysteine residues per monomer. The sequence also contains histidine- and cysteine-rich stretches, which could be involved in metal binding. Other

putative functions discussed for selenoprotein P are selenium transport and tissue-specific delivery or a reducing role.<sup>50</sup>

### 3.6 Selenophosphate Synthetase

Selenophosphate synthetase (SPS) catalyzes the synthesis of the activated selenium species required for the biosynthesis of selenocysteine (see below). The enzyme from *E. coli*, which was isolated first does not contain selenium.<sup>51</sup> It turned out, however, that in most other organisms, SPS is a selenocysteine-containing protein of about 37 kDa in which the selenocysteine occupies the position of a cysteine (Cys-17) in the *E. coli* homolog. Most mammalia possess two types of SPS homologs, one designated SPS II, which is a selenoprotein and possesses SPS activity; the other one, SPS I, has a threonine or arginine residue in the position of Cys-17 (*E. coli* nomenclature) and at least the arginine homolog lacks this activity. The actual function of SPS I is unknown. The reaction catalyzed by SPS is postulated to follow the sequence presented in equations (6) and (7).

Thus, the  $\gamma$ -phosphate group of ATP is transferred to some group of the protein and the enzyme phosphoryl intermediate is attacked by the selenide generating the only known direct phosphorus–selenium bond in biology. The ADP, which stays complexed to the enzyme is concomitantly hydrolyzed to AMP, and thus thermodynamically drives the overall reaction.<sup>51</sup> Sulfide does not serve as a substrate even at high concentrations, so SPS is one of the few enzymes that can discriminate between its Se substrate and the sulfur homolog. Recent evidence also indicates that the actual substrate is not free selenide but rather some selenium species generated from selenocysteine via the activity of one of the selenocysteine lyases present in the cell.<sup>52</sup>

## 4 CATALYTIC ROLE OF SELENOCYSTEINE

A question of particular interest concerns the catalytic advantage that a selenol in the active site of an enzyme has in comparison to a thiol group. It has been approached by replacing the selenocysteine in the formate dehydrogenase H by a cysteine residue and by determining the catalytic parameters of the Se-wild-type species with the mutant S-species. Table 1 presents the data obtained. They show that  $k_{\text{cat}}$  of the Se enzyme is more than 300-fold higher than that of the S variant and that the affinity to the substrate is only marginally affected.<sup>53</sup> Similar replacements of selenocysteine by cysteine in other enzymes like the deiodinase type I or methionine sulfoxide reductase B corroborated these results.

**Figure 4** Cascade of redox reactions catalyzed by mammalian thioredoxin reductase

**Table 1** Comparison of catalytic parameters of formate dehydrogenases

| Enzyme                             | $K_m$<br>(mM formate) | $k_{cat}$<br>(min <sup>-1</sup> ) | $k_{cat}/K_m$<br>(mM <sup>-1</sup> min <sup>-1</sup> ) |
|------------------------------------|-----------------------|-----------------------------------|--------------------------------------------------------|
| <i>E. coli</i> , N <sup>10</sup>   | 0.12                  | 33 800                            | $2.8 \times 10^5$                                      |
| <i>E. coli</i> , H                 |                       |                                   |                                                        |
| Se form <sup>9</sup>               | 26                    | 170 000                           | $6.5 \times 10^3$                                      |
| S form <sup>9</sup>                | 9                     | 540                               | $6.0 \times 10^1$                                      |
| <i>M. formicicum</i> <sup>54</sup> | not known             | 3100                              | —                                                      |

In *Methanobacterium formicicum*, the formate dehydrogenase can be considered as a natural S variant of the *E. coli* formate dehydrogenase H since it has 46% sequence similarity and a cysteine residue in the position where the *E. coli* enzyme contains a selenocysteine residue.<sup>1,54</sup> Its  $k_{cat}$ , although being sixfold higher than the *E. coli* S species, is almost 50-fold lower compared to the Se form. This protein makes about 3% of the total cellular protein of the methanogen, so it appears that the organism compensates for the low turnover number by synthesizing an increased amount of the enzyme.<sup>54</sup>

In several enzymes, the selenolate group of the selenocysteine residue participates in the coordination of a metal. The catalytic advantage of the liganding of the Ni in the active center of NiFe-hydrogenases via a selenolate to the protein backbone is still not clear since no isogenic mutant forms are available. A comparison of the catalytic performance of [NiFeSe] hydrogenases with [NiFe] hydrogenases led only to some suggestions: (1) [NiFeSe] enzymes may be more efficient in H<sub>2</sub> evolution; (2) they may be activated more easily; (3) the stability of a nickel-bound hydride intermediate may be decreased by the less electronegative selenium, which would increase the probability of a double H<sup>+</sup> exchange.<sup>22</sup> In formate dehydrogenases, the molybdenum, which bridges two pterin guanine dinucleotides, is coordinated to the selenolate of the selenocysteine of the  $\alpha$  subunit. In this case, the selenolate appears to directly participate in the reaction by facilitating the abstraction of a proton from the substrate.<sup>9,11</sup>

## 5 INCORPORATION OF SELENOCYSTEINE

### 5.1 A UGA Codon Directs Selenocysteine Insertion

A result emerging from the genetic analysis of selenoproteins was the discovery that selenocysteine is the 21st amino acid encoded in DNA.<sup>55</sup> Its insertion is directed by an in-frame UGA codon in the selenoprotein mRNA. UGA is used for this purpose in all three lines of descent (bacteria, archaea, and eukarya): The consistent use of UGA as a signal points to a common evolutionary origin of the selenocysteine coding system.

In the universal genetic code, UGA is one of the three stop codons that signal termination of polypeptide formation. Questions of basic biological relevance emerged from the use of this codon as the selenocysteine insertion signal: (1) What are the mechanisms which warrant that selenocysteine be inserted only at the position of this particular UGA codon, and not at the site of ordinary UGA termination codons? (2) Why does this particular codon not function as a termination signal? The investigation of the sequence context around this UGA did not reveal any peculiar features, which might contribute to its specificity. Rather, a secondary structure downstream of the UGA was found to be crucial (see below).

The existence of a special codon for selenocysteine implied that the amino acid is inserted cotranslationally. This was proved by means of gene fusions in which the 5' terminal portion of the fusion was derived from the formate dehydrogenase gene (including the TGA) and the 3' terminal portion was the *lacZ* reporter gene. The *lacZ* portion was translated into  $\beta$ -galactosidase only when the medium was supplemented with selenium although a full-length transcript was present in each case. Ribosomes, therefore, require selenocysteine to move into the *lacZ* mRNA portion.

### 5.2 tRNA<sup>Sec</sup> is Responsible for Decoding the UGA

A cotranslational mode of selenocysteine insertion necessitates the existence of a tRNA that carries this amino acid. This tRNA was identified during a screening for *E. coli* mutants blocked in selenoprotein formation.<sup>55</sup> The genes and the function of the gene products found to be involved in selenoprotein synthesis are listed in Table 2.

The product of the *selC* gene, tRNA<sup>Sec</sup>, was identified as a novel tRNA species. Its structure differs from the features of all elongator tRNAs.<sup>56</sup> With 95 nucleotides, it is the longest tRNA known to date. It has a variable loop of 22 nucleotides, an eight-base-pair aminoacyl acceptor stem, and a number of deviations from tRNA consensus structure. tRNA<sup>Sec</sup> is charged with L-serine by the cellular seryl-tRNA synthetase, which is responsible for aminoacylation of the serine isoacceptor species. Thus, selenocysteine is formed from a serine residue charged to tRNA<sup>Sec</sup>.

By chemical and enzymatic probing, the solution structure of this tRNA was analyzed. tRNA<sup>Sec</sup> is identical to other tRNAs concerning the T-arm and anticodon arm conformations, and the joining of the D- and T-loops by

**Table 2** *E. coli* genes and their products with a function in selenoprotein synthesis

| Gene | Product function        | Size             |
|------|-------------------------|------------------|
| SelA | Selenocysteine synthase | 10 × 50 kDa      |
| SelB | Translation factor      | 69 kDa (monomer) |
| SelC | tRNA <sup>Sec</sup>     | 95 nucleotides   |
| SelD | Selenium activation     | 37 kDa (monomer) |

**Figure 5** Structural features of the  $\text{tRNA}^{\text{Sec}}$  from *E. coli*. Elements involved in recognition by seryl-tRNA synthetase are shaded, antideterminants against recognition by EF-Tu are hatched. The modified bases are: D: dihydrouridine;  $\Psi$ : pseudouridine;  $i^6\text{A}$ : isopentenyl-adenosine; T: ribothymidine. Tertiary interactions involving base pairing are indicated by lines, those with intercalations by arrows

a tertiary Watson–Crick G19–C56 interaction. Its extra-long arm is double-stranded and closed by a four-nucleotide loop. It possesses novel interactions, namely, a G8–A21–U14 triple pair and an interaction between C16 of the D-loop and C59 of the T-loop. The D-arm has six base pairs instead of three, with the D-loop containing only four nucleotides. The interactions within the  $\text{tRNA}^{\text{Sec}}$  and for comparison, the  $\text{tRNA}^{\text{Ser}}$  structures are presented in Figure 5. Altogether, the results show that although  $\text{tRNA}^{\text{Sec}}$  displays the canonical L-shape in the three-dimensional structure, nature has used different sets of tertiary interactions to reach this structure.

### 5.3 Selenocysteine Biosynthesis

Displacement of the OH group of seryl- $\text{tRNA}^{\text{Sec}}$  by an –SeH group to yield selenocysteyl-tRNA requires the activation of the hydroxyl. When the *selA* gene product was purified, it was found that the protein contains pyridoxal phosphate as a prosthetic group. Accordingly, the reaction mechanism involves the formation of a Schiff base between the carbonyl of the pyridoxal moiety and the  $\alpha$ -amino group

of serine followed by 2,3-elimination of a water molecule, resulting in the formation of dehydroalanyl- $\text{tRNA}^{\text{Sec}}$ . Nucleophilic addition of selenide from selenophosphate as the selenium donor molecule then delivers selenocysteyl-tRNA.<sup>1,55</sup> Selenocysteine synthase is a decamer of 50 kDa subunits. Two of these subunits bind one seryl- $\text{tRNA}^{\text{Sec}}$  molecule. Electron microscopy at 20 nm resolution showed that the subunits are arranged with pentameric symmetry and that one tRNA molecule binds peripherally to two subunits.

In summary, selenocysteine is synthesized by the sequence of the reactions

where SS = selenocysteine synthase and SerS = seryl-tRNA synthetase. Selenophosphate synthesized by SSP (the *selD* gene product) also serves as an activated selenium species for another type of reaction, the conversion of 5-methylaminomethyl-2-thiouridine into 5-methylaminomethyl-2-selenouridine. This modified nucleoside is present in position 34 of the anticodon of  $\text{tRNA}^{\text{Glu}}$  and  $\text{tRNA}^{\text{Lys}}$  acceptor species, both from prokaryotes and eukaryotes.<sup>2</sup>

With regard to selenocysteine biosynthesis in archaea and eukarya, a tRNA has been known for some time, which accepts L-serine and possesses an anticodon complementary to UGA.<sup>5</sup> It shares a number of structural features with  $\text{tRNA}^{\text{Sec}}$  from *E. coli*, such as extended aminoacyl acceptor and D-arms. In eukarya, the serine residue attached to this tRNA can be phosphorylated by a specific kinase and it was first assumed that this tRNA inserts phosphoserine into proteins. However, closer examination revealed that this tRNA carries selenocysteine in vivo and certainly is the pendant to  $\text{tRNA}^{\text{Sec}}$  from *E. coli*. It is still elusive whether O-phosphoserine-tRNA is the biosynthetic intermediate for selenocysteyl-tRNA formation in eukaryotes; also, there is no evidence yet of an eukaryal and archaeal enzyme, equivalent in its function to selenocysteine synthase from bacteria.

### 5.4 SelB, a New Translation Factor

Mutants of *E. coli* with a lesion in the *selB* gene were unable to synthesize selenoproteins although they accumulated selenocysteyl-tRNA<sup>Sec</sup> in vivo. This indicated a function of SelB in the decoding process itself. The following experimental results revealed that SelB is a translation factor, specialized for selenocysteyl-tRNA<sup>Sec</sup>: (1) SelB, over its N-terminal two-thirds, displays sequence homology with translation factors such as EF-Tu and IF2 $\alpha$ ; (2) SelB, like other

translation factors, is a guanine nucleotide-binding protein; (3) SelB binds selenocysteyl-tRNA<sup>Sec</sup>. The precursor species, seryl-tRNA<sup>Sec</sup> is not recognized, a fact which contributes to the specificity of insertion. EF-Tu binds selenocysteyl-tRNA with less than 1% of the affinity with which it binds aminoacyl-tRNAs of one of the 20 classical amino acids. This indicates that SelB has a function which is distinct from that of EF-Tu. Thus, EF-Tu forms a ternary complex with one of the 20 standard amino acids and GTP, whereas SelB forms an equivalent complex with selenocysteyl-tRNA and GTP.<sup>57</sup>

Regarding the structural features that enable EF-Tu and SelB to distinguish 'their' tRNAs, an extensive mutational analysis was performed and synthetic RNA 'minihelices' were analyzed for binding to EF-Tu and SelB. It was found that both the length of the aminoacyl-tRNA acceptor stem and the basal helical part of the acceptor arm were crucial.<sup>58</sup>

### 5.5 mRNA Determinants Required for Decoding UGA with Selenocysteine

In those genes that code for selenoproteins, TGA (UGA) directs the insertion of selenocysteine in all biological systems studied. The question of the recognition of the UGA as a signal for selenocysteine insertion was approached by a mutational analysis. Deletions introduced upstream and downstream of the UGA within the formate dehydrogenase H and N genes revealed the requirement of a segment of 40 nucleotides downstream of the codon.<sup>59</sup> A stable RNA hairpin structure (the SECIS element) can be formed within this RNA segment. The functional role of this hairpin in the selenocysteine decoding process has been proved by genetic and biochemical strategies. It was found that an intact secondary structure with a sequence determinant residing within a single-stranded (loop) region serves as a recognition element for differentiating the selenocysteine-specific UGA codons, thus providing evidence that it is the mRNA context that directs tRNA<sup>Sec</sup> to decode this position. The nature of the codon/anticodon sequence is irrelevant, the only requirement is that they are complementary.

On the basis of a dual function of UGA as a codon for selenocysteine insertion and for translation termination within a single cell, it has to be assured (1) that this UGA codon is not used as a termination signal and (2) that selenocysteyl-tRNA is directed only to this position. The results of a biochemical analysis indeed revealed that this is achieved by the formation of a complex between SelB, selenocysteyl-tRNA, and the stem-loop structure downstream of the UGA. The binding to the SECIS element was shown to involve an ultimate 17-kDa C-terminal domain of SelB.

The interaction of SelB with its ligands was analyzed by stopped flow methods. The main finding was that binding of the two RNA ligands (selenocysteyl-tRNA and the SECIS element) confers to the SelB protein, a conformation that

**Figure 6** Pathway of selenocysteine biosynthesis and incorporation into protein as resolved for *E. coli*; for details, see text

renders it compatible for interaction with the ribosome. Upon this interaction, GTP is hydrolyzed and the charged tRNA is released in the vicinity of the ribosomal A site. This scenario explains why ordinary UGA stop codons are not translated: since they lack a SECIS element in their vicinity, SelB (which is not complexed to the mRNA) does not possess the productive conformation for the decoding process.<sup>57</sup>

Figure 6 summarizes the steps of selenocysteine synthesis and incorporation, as elucidated for the *E. coli* system.

In mammalia, a recognition element of selenoprotein mRNAs (SECIS) exists within the 3' untranslated region, and the UGA within the selenoprotein mRNAs is decoded with selenocysteine only when the 3' untranslated region is present.<sup>5</sup> Substitution of the homologous 3' region by that of another selenoprotein mRNA allows selenocysteine insertion again. The eukaryal SECIS element is the binding target for a protein designated SBP2 (SECIS element binding

protein 2). SBP2 undergoes protein–protein interaction with a eukaryal homolog of the bacterial translation factor SelB.<sup>6</sup> This interaction is stabilized in the presence of selenocysteyl-tRNA.<sup>60</sup> Therefore, in analogy to the bacterial system, the function of SelB is taken over by two proteins and their stable interaction requires the binding of the charged tRNA thus resembling the formation of the stabilized quaternary complex of SelB.

## 6 DESIGN OF NEW SELENOPROTEINS

The construction of synthetic selenocysteine-containing proteins or selenium-containing proteins attracts considerable interest at present, mainly for the reason that it can be used to solve the phase problem in X-ray crystallography. Selenomethionine incorporation has been used mostly until now for this purpose. There are also two reports on new synthetic selenocysteine-containing proteins. In one case, the active site serine of subtilisin has been converted into a selenocysteine residue by chemical means, with the result that the enzyme gains a predominant esterase instead of protease activity. In the second case, automated peptide synthesis was carried out to produce a peptide in which all seven-cysteine residues of the *Neurospora crassa* metallothionein (Cu) were replaced by selenocysteine. The replacement resulted in an alteration of both the stoichiometry and the affinity of copper binding.<sup>2</sup>

Future investigations will concentrate on the replacement of cysteine residues by selenocysteine using biological methods. Thus, a system has been established to substitute all cysteine residues of a protein in an overexpression system and it has been used successfully in structural analysis of cysteine-rich proteins and also to replace an active site cysteine by selenocysteine.<sup>61,62</sup> A strategy for the replacement of both methionine and cysteine by their selenium homologs has also been developed recently.<sup>63</sup> It may also be possible, however, to use the information on selenoprotein synthesis in bacteria to achieve targeted replacement of a selected, single cysteine residue. In rare cases, a change of the mRNA sequence by the introduction of silent mutations may be possible to create the determinants necessary for interaction with the translation factor SelB. To this end, a cysteine codon has to be changed to a UGA codon and the 3' flanking region has to be altered such that the stem-loop structure determining selenocysteine incorporation is generated. This approach, of course, suffers from the strict sequence constraints that may preclude the formation of this mRNA recognition element and may be open for application only in special cases. Thus, the methionine sulfoxide reductase gene from mammalia has been engineered such that the UGA is followed by the *E. coli* consensus SECIS element in the mRNA and in this way recombinant production of the eukaryal enzyme in *E. coli* could be achieved.<sup>64</sup> Also, recombinant mammalian

thioredoxin reductase (in which the selenocysteine is the penultimate C-terminal amino acid residue) could be produced in *E. coli* by fusing the *E. coli* SECIS element downstream of the termination codon of the thioredoxin reductase gene.<sup>65</sup>

## Glossary

*Accumulation region:* the region near a semiconductor interface where negative charges (for an *n*-type semiconductor) accumulate

*Band bending diagram:* electric potential energy versus distance diagram of a semiconductor contact

*Barrier height energy:* the energy difference between the bottom of the conduction band of the semiconductor at the interface and the Fermi level of the contacting phase. It is the activation energy required to transfer charge from the contacting phase to the semiconductor

*Built-in voltage:* the absolute value of the difference between the electric potential of an electron at the semiconductor surface and an electron in the bulk of the semiconductor

*Current–voltage properties:* dependence of the observed current on the applied potential

*Depletion approximation:* an approximation that assumes that the net concentration of charges in the depletion region is equal to the dopant concentration. This concentration is constant throughout the depletion region. Furthermore, there are no uncompensated charges in the quasineutral region

*Depletion region:* a charged region of width *W* at the semiconductor interface consisting of fixed positive charges (for an *n*-type semiconductor)

*Depletion width:* the depth of the depletion region in a semiconductor

*Diode equation:* the equation that describes the relationship between the applied bias and the resulting current of a semiconductor contact. It is generally of the form  $I = -I_0(\exp(-qV/kT) - 1)$  where  $I_0$  is the equilibrium exchange current and  $V$  is the applied bias

*Electrochemical potential:* quantity that describes the thermodynamic tendency of a phase to gain or lose electrons to another phase

*Exchange current:* the microscopic current crossing a semiconductor interface in either direction at equilibrium

*Fermi level:* the energy level where the probability of finding an electron is 1/2

*Fermi level pinning:* the ability of surface states to ‘buffer’ the Fermi level of the semiconductor from changes in the electrochemical potential of the contacting phase

*Forward bias:* the sign of the applied potential that results in an exponential increase in the current passing through a semiconductor junction

*Homojunction:* a junction formed between two identical semiconductors of different doping densities or dopant atoms

*Quasineutral region:* the region in a semiconductor where the net charge density is zero

*Rectification:* the asymmetric current–voltage characteristics of a semiconductor junction, in which charge-carrier flow is impeded in one direction, but not in the other direction

*Reverse bias:* the sign of the applied potential opposite to forward bias. In reverse bias, the current through a diode is essentially independent of the applied potential

*Schottky barrier:* a rectifying semiconductor/metal junction

*Surface states:* energy levels arising from atoms at the semiconductor surface

*Work function:* the minimum energy required to remove an electron from a phase to vacuum

$A_s$  = surface area of a semiconductor contact;  $[A^-]$  = concentration of the reduced form of a redox couple in solution;  $[A]$  = concentration of the oxidized form of a redox couple in solution;  $A^{**}$  = effective Richardson constant;  $E(A/A^-)$  = electrochemical potential of a solution;  $E_{cb}$  = energy of the conduction band edge;  $E_F$  = Fermi level;  $E_{F,m}$  = Fermi level of a metal;  $E_{F,sc}$  = Fermi level of a semiconductor;  $E(A/A^-)$  = redox potential of a solution;  $E^{\circ}(A/A^-)$  = formal redox potential of a solution;  $\mathcal{E}$  = electric field;  $\mathcal{E}_{max}$  = maximum electric field at a semiconductor interface;  $e$  = number of electrons transferred per molecule oxidized or reduced;  $F$  = Faraday constant;  $I$  = current;  $I_0$  = exchange current;  $k$  = Boltzmann constant;  $k_{et}$  = intrinsic rate constant for electron transfer at a semiconductor/liquid interface;  $k_n$  = forward electron transfer rate constant;  $k_n^{-1}$  = reverse electron transfer rate constant;  $N_d$  = concentration of donor atoms in an *n*-type semiconductor; NHE = normal hydrogen electrode;  $n$  = electron concentration;  $n_b$  = electron concentration in the bulk of a semiconductor;  $n_s$  = electron concentration at a semiconductor surface;  $n_{so}$  = electron concentration at the surface of a semiconductor under equilibrium conditions;  $Q$  = charge per unit area;  $q$  = elementary charge;  $R$  = gas constant; SCE = saturated calomel electrode; sc = semiconductor;  $T$  = temperature;  $V$  = electric potential;  $V_{bi}$  = built-in voltage;  $V_n$  = the potential difference between the Fermi level and the conduction band energy in the semiconductor bulk;  $W$  = depletion width in a semiconductor;  $x$  = distance;  $\epsilon_s$  = static dielectric

constant;  $\varphi$  = work function;  $\phi_b$  = barrier height;  $\lambda$  = nuclear reorganization energy for an interfacial electron transfer process.

## 1 INTRODUCTION

Semiconductors are technologically important, in large part due to their unique electrical and optical characteristics (see *Semiconductors*). However, the construction of practical devices from semiconductors generally requires the formation of electrical contacts. The nature of these biphasic electrical contacts can modify, and can sometimes completely determine, the electrical and optical characteristics of the resulting device.<sup>1</sup> For example, contacting *n*-type Si with indium yields an ohmic, resistive electrical contact that freely passes current in both directions, whereas contacting *n*-type Si with gold yields a rectifying contact that passes current freely in one direction but effectively prevents its flow in the other direction.<sup>2</sup> Similarly, Si/HF(aq) junctions are useful for lithographically patterning and etching Si, while Si/methanol junctions provide the basis for efficient, stable, photoelectrochemical solar energy conversion devices.<sup>3,4</sup> Clearly, an understanding of the chemistry of semiconductor surfaces, and of contacts to these surfaces with other phases, is an important component in the design of any semiconductor-based device.<sup>5–8</sup> This article is therefore devoted to a description of the basic chemical and physical properties of semiconductor contacts.

The distinguishing feature of a semiconductor contact is the electric field that is present in the vicinity of the junction. Whenever two phases are brought into contact, charge must flow across the interface until the electrochemical potential of both phases is identical at all points in space. For example, when two metals are brought into contact, charge flows in response to the contact potential difference between the two phases. After this equilibration process has occurred, the physical characteristics of the metallic phases are essentially unchanged, because any excess charge at the metal/metal interface is screened in the first atomic layers of the metals (Figure 1). For contacts to semiconductors, however, the charge is not completely screened at the semiconductor surface, and an electric field is present in the semiconductor. A large interfacial electric field will generally induce a change in the charge-carrier concentration near the semiconductor surface. A large electric field will also direct and accelerate the motion of charge carriers, and can produce a nonzero flux of charge carriers toward the junction. Such effects can dramatically change the properties of the resulting semiconductor devices. For these reasons, chemical control over the electric fields at semiconductor contacts is desirable in essentially all semiconductor devices.

**Figure 1** Charge transfer equilibration processes. (a) At a metal/metal' junction; all the required charge is held within the first few layers of the junction. (b) At a metal/semiconductor junction; the charge arises from the ionization of dopant atoms, and produces an electric field in the bulk of the semiconductor

The focus of this article will be to describe, first qualitatively and then quantitatively, the electrical properties of semiconductor contacts. The goal is to understand the origin of the electric field at semiconductor contacts, to describe the field strength as a function of distance into the semiconductor bulk, and to understand the effects of the interfacial field on the current–voltage characteristics of the device. This discussion will be presented from a general perspective, and will be applicable to semiconductor/metal, semiconductor/liquid, semiconductor/semiconductor, and semiconductor/conducting polymer contacts. The discussion will provide an understanding of the principles behind the operation of diodes, transistors, photovoltaic cells, photoelectrochemical cells, light-emitting devices, and other technologically important semiconductor devices.

## 2 EQUILIBRIUM STATE AT A SEMICONDUCTOR JUNCTION

In its simplest terms, the charge transfer between a semiconductor and a contacting phase is no different from the charge transfer between atoms to form an ionic bond. For example, chemists realize that a neutral sodium atom will transfer charge when it encounters a neutral chlorine atom, because Na has a low electronegativity and Cl has a high electronegativity. The bond formation between these atoms results in an equilibrium state in which the compound NaCl is best represented with an ionic bond, that is,  $\text{Na}^+\text{Cl}^-$ . It is also obvious to chemists that the difference in electronegativities of the atoms will

determine the degree of charge transfer in the molecule, with HCl having a much more covalent bond than NaCl.

The charge transfer reaction between two phases is governed by similar principles. However, the controlling factor in this situation is the electrochemical potential. Whenever two phases of differing electrochemical potentials are brought into contact, the phase that has a more negative electrochemical potential will tend to lose electrons to the phase with a more positive electrochemical potential (see **Semiconductors** for the sign convention on the electrochemical energy scale). Net charge transfer between the two phases will then occur until equilibrium is established.

At equilibrium, one phase will have an excess of positive charge, and the other phase will have an excess of negative charge. The initial difference in electrochemical potentials between the two phases will determine the degree of charge transfer across the phase boundary, much as the difference in electronegativity indicates the degree of bond ionicity in molecules formed from neutral atoms. The only conceptual difference between the molecular case and the semiconductor contact is that a physical junction between the semiconductor and the contacting phase provides an obvious dividing line to separate the phase that loses electrons from the phase that gains them.

In most of our examples, the semiconducting solid will be one of the phases that is undergoing charge transfer. A metal, with its high density of electronic states available to accept or donate charges, will be the other phase. An analogous treatment can be used to describe the charge transfer at semiconductor/liquid, semiconductor/polymer, and semiconductor/semiconductor contacts, but the semiconductor/metal contact is the simplest to describe conceptually. These different contacts have quantitative differences in the actual degree of charge transferred upon equilibration, but the qualitative principles are the same in all cases. Whenever possible, the discussion will be generalized to cover all of the junction types, with specific features of the different junctions discussed where appropriate.

## 2.1 Depletion

### 2.1.1 Qualitative Description of Interfacial Charge Equilibration

The simplest case to consider is the situation that describes the contact between an *n*-type semiconductor and a metal. As discussed above, the factor that controls the charge transfer process is the electrochemical potential, or Fermi level,  $E_F$ , of each phase.<sup>9</sup> The initial difference in the electrochemical potentials of the two phases indicates that, after contact, charge must flow between the phases in order to reach equilibrium. We will consider the case where the electrochemical potential of an isolated *n*-type semiconductor ( $E_{F,sc}$ ) is more negative than the electrochemical potential of an isolated metal phase

**Figure 2** Charge transfer equilibration processes at semiconductor/metal junctions. (a) Before equilibrium is established, the entire semiconductor is neutral. (b) At equilibrium, a positively charged region of width  $W_1$  is present in the semiconductor. (c) Similar to (a), except that the Fermi level in the metal ( $E_{F,m}$ ) is farther from vacuum (more positive) than in (a). (d) Similar to (b), but the charged region extends deeper into the semiconductor ( $W_2 > W_1$ ), because the number of charges that must cross the semiconductor/metal interface is greater. In both (b) and (d), the positions of the conduction and valence band edges are unchanged by the charge equilibration processes

( $E_{F,m}$ ) (Figures 2a and c). In this situation, charge will leave the semiconductor, because it has a more negative initial electrochemical potential ( $E_{F,sc} < E_{F,m}$ ). This charge will be accepted by the metal phase, which has a more positive electrochemical potential.

As a result of this initial difference in electrochemical potentials, the transfer of electrons across the semiconductor/metal junction disrupts the original charge neutrality of the semiconductor and the metal. This interfacial charge-transfer process produces an excess of positive charges in the semiconductor and an excess of negative charges in the metal (Figures 2b and d). In essence, a capacitor is charged during this process, and the components of the capacitor are the electrons in the metallic phase and the positive charges in the semiconducting phase. This charging process continues until the initial difference in electrochemical potentials is neutralized, that is, until the capacitor is sufficiently charged that no further net charge transfer is thermodynamically possible. At this point, equilibrium is attained between the two phases. At equilibrium, electric fields and electric potential gradients are present in both the semiconducting and metallic phases, since neither phase is electrically neutral.<sup>10</sup>

In general, the addition of excess negative charges to a phase will tend to decrease the value of its electrochemical potential (i.e. shift  $E_F$  more negative). This can be rationalized because it is easier to ionize a phase with excess negative charges than one without such an excess. For an arbitrary phase in contact with a semiconductor, it is not always possible to predict a priori whether the Fermi level of the semiconducting phase will move more or less than that of the contacting phase. However, for semiconductor/metal contacts, it is possible to predict what will occur. The number of available electronic states per unit energy in the metal far exceeds the number present in a semiconductor, because the semiconductor has essentially no available states in its band gap region.<sup>9</sup> Consequently, the capacitance of the metal phase is much larger than the capacitance of the semiconductor phase. Thus, during the equilibration process, a relatively small percentage of the available states in the metal are filled and there is little negative movement of the electrochemical potential of the metal. The Fermi level of the  $n$ -type semiconductor, however, shifts positively until it reaches the value of the metal Fermi level. In chemical terms, the metal acts as an excellent ‘buffer’ of energy with respect to the excess charge. This situation is analogous to aqueous buffers that resist changes in pH when mixed with nonbuffered solutions that contain small amounts of  $H^+$ .

The equilibrium positions of the Fermi level for both the semiconducting and the metallic phases are therefore essentially equal to the initial value of the electrochemical potential of the metal,  $E_{F,m}$  (Figure 2). When sufficient charge has transferred across the interface to produce this change in  $E_{F,sc}$ , equilibrium is reached, and no further net flow of charge across the metallurgical boundary will occur.

Without any additional quantitative information, some important chemical trends in junction behavior can be clearly understood. In a molecule, a large difference in electronegativity between bonded atoms leads to a large degree of ionicity in the bond. A greater initial difference in the electrochemical potentials of the isolated semiconducting and metallic phases should therefore produce a greater propensity for interfacial charge transfer at the semiconductor/metal junction. Using our example of an  $n$ -type semiconductor, metals with more positive electrochemical potentials produce greater initial contact potentials to a given semiconductor surface. These metals would thus be expected to produce larger degrees of interfacial charge transfer than metals with less positive electrochemical potentials (Figure 2). Similarly, an  $n$ -type semiconductor with a more negative Fermi level, that is, either a more highly doped sample of a given material, or a semiconductor with a more negative conduction band edge at a similar doping level, would be expected to produce a greater degree of charge transfer when placed in contact with a given metal. This chemical control over the charge-transfer process is one of the key experimental features of semiconductor contacts.

### 2.1.2 Depletion Width

An important quantity, the depletion width ( $W$ ), can also be understood using these qualitative concepts. For a doped semiconductor, charge-transfer equilibration removes carriers from the sites that are most easily ionized. Thus, charge is typically removed from the dopant atoms, as opposed to being removed from atoms of the semiconductor material. For example, in phosphorous-doped  $n$ -type Si, charge-transfer equilibration would be accomplished by transferring the easily ionizable fifth valence electron from the P dopant atoms, as opposed to transferring electrons arising from ionization of the Si lattice atoms (see **Semiconductors**). In order to reach charge transfer equilibrium, a certain number of charges must be pulled out of the semiconducting solid. The number of charges is generally far larger than the number of dopant atoms present in one atomic layer of the semiconductor.<sup>1</sup> Thus, as depicted in Figures 2(b) and (d), greater degrees of charge transfer require that we ‘reach further into’ the bulk of the semiconductor to obtain the proper number of ionizable charges from the semiconductor.

The depth over which dopants are ionized can be readily calculated. For an  $n$ -type semiconductor of majority carrier density  $N_d$ , a good first approximation is that charge transfer produces a fixed concentration of charged dopant atoms for a depth  $W$ . Within this depth, essentially all of the electrons donated by the available dopants have been removed from the semiconductor, and the ionized dopant atoms are left in this region as fixed positive charges. Beyond this depth, however, essentially no electrons have been removed, and the ionized dopants are neutralized by the surrounding electrons. This approximation is called the depletion approximation.<sup>10</sup> In the semiconductor, the charged region of width  $W$  is called the depletion region.

With this approximation,  $W$  is readily calculated if the amount of charge transferred per unit area,  $Q$ , is known. The value of  $W$  is then simply  $Q/N_d$ . When a higher dopant density is available for donating electrons to the metal, one needs to ‘reach in’ less deeply into the semiconductor to achieve the same degree of charge transfer. Thus, for a given initial contact potential, the value of  $W$  becomes smaller as the dopant density increases.  $W$  will be an important quantity to understand when considering the effects of various chemical modifications on the behavior of semiconductor/metal interfaces. An accurate calculation of  $W$ , using the depletion approximation, depends only on a prediction of the amount of charge per unit area,  $Q$ , that must be transferred to equilibrate the desired semiconductor/metal interface.

### 2.1.3 Quantitative Description of Interfacial Charge Equilibration

It is also important to understand quantitatively the strength of the electric field, and the values of the electric potential that are produced as a result of this charge-transfer equilibration

process. Simple electrostatic considerations suggest that an electric field and an electric potential will be present in the semiconductor, because the interfacial charge transfer has removed negative charges from an initially neutral phase to produce a net positive charge density in the semiconductor portion of the junction.<sup>11</sup> Our goal now is to describe quantitatively the electric field and electric potential at a semiconductor junction.

The relationship between the charge density and the electric field strength is obtained from electrostatics. Consider a negative test charge that we will bring through the semiconductor and toward the semiconductor/metal interface. Within the bulk of the semiconductor, the negative charges on the metal side of the interface are offset (i.e. screened) by an approximately equal number of positive charges in the depletion region of the semiconductor. Thus, negligible electric fields are experienced by this test charge. This region is called the quasineutral region of the semiconductor, as a negative test charge in the bulk of the semiconductor is not influenced by the presence or absence of charge transfer at the semiconductor/metal interface.

As we move our negative test charge closer to the semiconductor/metal interface, it will penetrate the depletion region. This negative test charge will then be repelled from the interface, because it will experience the repulsion of those negative charges in the metal, which are not screened by the positive charges in the semiconductor. Another way of thinking about this situation is that there is now a net dipole acting on the test charge, and this dipole repels the charge from the interface. This net dipole arises from the excess of negative charges that are sensed by the test charge when it is located within the depletion region.

The presence of this electric dipole implies that work is required to push this negative test charge toward the interface. We can quantitatively express this work either in terms of the electric field strength at each position in the semiconductor, or in terms of the electric potential at each position of the system. According to electrostatics, the electric field is proportional to the integral of any excess charge density along the path of interest.<sup>11</sup> Thus, using the depletion approximation, which states that the charge density is simply the dopant density for all values of distance,  $x$ , up to the depletion width, we calculate that:

$$\mathcal{E}(x) = \left( \frac{qN_d}{\epsilon_s} \right) x \quad (1)$$

where  $\mathcal{E}(x)$  is the electric field at position  $x$  in the semiconductor,  $\epsilon_s$  is the static dielectric constant of the semiconductor,  $q$  is the elementary charge, and  $N_d$  is the dopant density of the  $n$ -semiconductor. In equation (1), the origin of the  $x$ -axis has been defined as the position that separates the depletion region from the quasineutral region; therefore, the semiconductor/metal interface is at a distance  $W$  ( $W > 0$ ) from the origin (Figure 3).

**Figure 3** The spatial dependence of the charge density, the electric field, and the electric potential in the semiconductor at equilibrium for an  $n$ -type semiconductor/metal junction, where all of the voltage is dropped in the semiconductor space-charge region. The origin of the  $x$ -axis is chosen for convenience as the point closest to the interface where the net charge in the semiconductor equals zero. (a) The distance dependence of the charge density under the depletion approximation. (b) The electric field as a function of distance. Note that the maximum electric field occurs at the semiconductor/metal interface. (c) The distance dependence of the electric potential. The electric potential in the bulk of the semiconductor has been defined as zero. Because the sign of the electric field strength is positive, the electric potential at the interface is more negative than in the bulk

As given in equation (1), since the depletion approximation ensures that the charge density in the depletion region is independent of distance, the electric field in this region increases linearly as it approaches the semiconductor/metal junction. The maximum electric field in the semiconductor ( $\mathcal{E}_{\max}$ ) is obtained at the position  $x = W$ :

$$\mathcal{E}_{\max} = \left( \frac{qN_d}{\epsilon_s} \right) W \quad (2)$$

Thus, the maximum electric field in a semiconductor/metal junction is located at the interface. This is an important feature for constructing numerous devices using semiconductor junctions, because the maximum ability for charge separation by the electric field occurs at the junction.

An alternate and convenient method of expressing the work required to push the negative test charge toward the interface is given by the electric potential at each point in the semiconductor. Electrostatics states that the electric potential is equal to the negative integral of the electric field over the path of interest.<sup>11</sup> Thus, integrating the linear electric field (equation 1) from the bulk of the semiconductor toward the semiconductor/metal interface yields a quadratic expression for the electric potential in the semiconductor phase:

$$V(x) = -\left(\frac{qN_d}{2\epsilon_s}\right)x^2 \quad (3)$$

The electric potential of an electron near the interface is thus higher than that of an electron in the bulk. The negative sign in equation (3) merely indicates that the electric potential at the interface is more negative than that in the bulk. This makes sense, because work is required to push the negative test charge toward the interface. The difference in electric potential between the quasineutral region and any other position is a quantitative measure of the work required to move this test charge in the semiconductor.

A similar treatment can be used to calculate the electric field and the electric potential in the metal. However, in a metal, both the electric field and the electric potential drop to zero at a very short distance from the semiconductor/metal interface.<sup>2</sup> This occurs because metals do not support electric fields, and all of the excess charge density resides on the surface of the metallic phase.<sup>9</sup> The surface dipole layer is therefore effectively screened from test charges at any finite distance into the metallic phase, and the width of the electric potential gradient is extremely small. Because charge carriers can pass freely through this extremely thin barrier, only the electric field in the semiconductor significantly affects the electrical properties of semiconductor/metal contacts.

Combining all of these concepts, we can concisely express the electrostatic situation for any semiconductor/metal contact at equilibrium. Figure 3 contains plots of the charge density, electric field, and electric potential versus distance for such a semiconductor/metal junction. Because these diagrams are all related to each other, only one type of diagram is often depicted when a particular semiconductor/metal interface is discussed. The most convenient diagram is that of the electric potential energy versus distance, because the electric potential energy can be directly related to the potential energy of an electron at any point in the system. The potential energy of an electron at each position in the semiconductor can be obtained by multiplying the electric potential by the charge on an electron.

**Figure 4** An energy diagram of an *n*-type semiconductor/metal junction. (a) Before charge equilibration occurs, the energy levels of the semiconductor conduction and valence bands are uniform at all points along the *x*-axis. (b) After charge equilibration has occurred, a depletion layer (*W*) is formed in the semiconductor. The electric potential energy levels of  $E_{cb}$  and  $E_{vb}$  are dependent on the distance into the depletion region. However, at equilibrium, the electrochemical potential is the same in the metal and at all points in the semiconductor (i.e.  $E_{F,m} = E_{F,sc}$ ).  $qV_n$  is defined as the difference between  $E_{F,sc}$  and  $E_{cb}$  in the bulk of the semiconductor.  $V_{bi}$  is the built-in voltage of the junction and  $\phi_b$ , the barrier height, is defined as  $\phi_b = V_n + V_{bi}$ .

A schematic of the energy versus distance relationship for a semiconductor/metal junction before and after equilibration is depicted in Figure 4. These potential energy versus distance diagrams are often called band bending diagrams. The electric potential gradient leads to a quadratic increase in the potential energy of an electron in the semiconductor as it approaches the semiconductor/metal junction. Both the conduction and valence bands are shown bent because the electric field acts equally well on test charges that are in either band. Note also that on these diagrams, the distance between the bottom of the conduction band and the top of the valence band always remains constant. This situation results because the presence of an electric field has a negligible effect on the value of the band gap for most semiconductors.<sup>9</sup>

Another chemical analogy is useful in elucidating the meaning of band bending diagrams. Chemists are quite comfortable with reaction coordinate diagrams, in which the free energy of the system is plotted versus some (typically

unknown) reaction coordinate for a chemical reaction. A similar interpretation is possible for band bending diagrams (Figure 4b). These diagrams can be interpreted as representing the activation energy required to move a negative charge along a reaction coordinate toward the interface. This movement will require energy, because of the repulsion due to the unscreened negative charges on the metallic side of the semiconductor/metal junction. The difference between the common chemical reaction coordinate diagram and a band bending diagram is that if the amount of charge is known, the electric potential (equation 3), and therefore the electric potential energy of the system, can be calculated precisely at each point along the reaction coordinate. In contrast, typical chemical reaction coordinates are schematic in both energy and in direction along the bond coordinates.

A few quantitative values are worth deriving in order to complete the diagrams of Figure 4. According to equation (3), the absolute value of the electric potential reaches its maximum at the interface ( $x = W$ ). The absolute value of this potential difference between the interface and the semiconductor bulk is called the built-in voltage ( $V_{bi}$ ). The built-in voltage is a direct result of the initial electrochemical potential difference between the semiconductor and the metal, with  $V_{bi} = (|E_{F,sc} - E_{F,m}|)/q$  (Figure 4). This quantity is the total change in electric potential that would be experienced upon moving a test charge from the back of the semiconducting solid ( $x = -\infty$ ) all the way to the interface between the semiconductor and the metal ( $x = W$ ). The quantity  $V_{bi}$  is called the built-in voltage because this voltage is 'built-in' to the semiconductor as a result of equilibration of the semiconductor Fermi level with the electrochemical potential of the metal.  $V_{bi}$  can be related to the amount of charge transferred, and therefore, to the depletion width,  $W$ , using the equations developed above. From equation (3):

$$V_{bi} = \left( \frac{q N_d}{2\epsilon_s} \right) W^2 \quad (4)$$

$$W = \sqrt{\frac{2\epsilon_s V_{bi}}{q N_d}} \quad (5)$$

Another quantity of interest on the band bending diagrams refers to the bulk of the semiconductor. In the semiconductor quasineutral region where no electric fields are present, the difference between the Fermi level and the energy of the bottom of the conduction band remains the same as it was in the neutral semiconductor before equilibration with the metal. Thus, we can define  $V_n \equiv (E_{F,sc} - E_{cb})/q$  as the potential difference between the Fermi level and the conduction band energy in the semiconductor bulk, as shown on the band bending diagram in Figure 4.

The difference between the equilibrium Fermi level energy and the energy of the bottom of the conduction band at the semiconductor/metal interface is also an important quantity often mentioned in literature.<sup>10</sup> This difference is called

the barrier height energy of the junction and is generally abbreviated as  $q\phi_b$ , where  $\phi_b$  is the barrier height in V, and  $q\phi_b$  is the barrier height energy in eV, that is,  $q\phi_b = E_{F,m} - E_{cb}$  (at the electrode surface). From Figure 4(b) and from the definitions of  $V_{bi}$  and  $V_n$ , it can also be seen that  $\phi_b = V_n + V_{bi}$ . It is generally convenient to use  $\phi_b$  to characterize the barrier height of semiconductor/metal contacts, because unlike  $V_n$  and  $V_{bi}$ ,  $\phi_b$  is independent of the doping level of the semiconductor. In fact, the magnitude of  $\phi_b$  depends only on the initial position of the semiconductor conduction band,  $E_{cb}$ , and on the initial electrochemical potential of the metal,  $E_{F,m}$ .

A final quantitative aspect of band bending diagrams concerns the equilibrium concentration of electrons at different positions in the semiconductor. Again we will refer to semiconductor/metal contacts in developing the equations, but analogous expressions are available for the other types of contacts as well. Before contact with another phase, the carrier concentration is equal at all points in the semiconductor. For a moderately doped semiconductor with completely ionized dopants, this carrier concentration is simply given by the quantity  $N_d$ . However, for a depleted  $n$ -type semiconductor/metal contact, the presence of unshielded negative charge on the metallic side of the interface will make it energetically difficult to support the negatively charged electrons in the semiconductor depletion region. Because the screening of interfacial charge is a function of distance away from the semiconductor/metal junction, the actual majority carrier concentration in a depleted semiconductor is expected to be a function of distance from the semiconductor/metal interface.

To obtain an expression for this carrier concentration versus distance relationship, we need to consider the potential energy difference between various points in the semiconducting solid. The relationship between the bulk carrier concentration,  $n_b$ , and the carrier concentration at any other position in the semiconductor can be obtained simply by using the Boltzmann equation:

$$n(x) = n_b \exp\left(\frac{qV(x)}{kT}\right) \quad (6)$$

where  $V(x)$  is the electric potential at any position of interest relative to the bulk semiconductor. The concentration of electrons in the bulk is the same as that in the neutral material, so  $n_b = N_d$ . The quantity  $V(x)$  is negative with respect to the potential of the conduction band in the quasineutral region of the semiconductor (Figure 3c, equation 3). Therefore, as the semiconductor/metal interface is approached,  $n(x)$  decreases exponentially from the bulk electron concentration. An identical expression can be applied to semiconductor/semiconductor and to semiconductor/liquid contacts, once  $V(x)$  is known for the system of interest.

From equation (6), it can be seen that  $n(x)$  reaches a minimum at the semiconductor surface. The concentration of

electrons at the surface,  $n_s$ , is given by

$$n_s = n_b \exp\left(-\frac{qV_{bi}}{kT}\right) \quad (7)$$

where  $V_{bi}$  is the absolute value of  $V(x)$  at  $x = W$ . This expression clearly shows that  $V_{bi}$  represents the total electric potential barrier for electrons to move from the bulk of the semiconductor to the metal. As will be discussed in later sections, the surface concentration of electrons ( $n_s$ ) is an important factor that controls the charge transfer events between the semiconductor and the contacting phase. Thus,  $V_{bi}$  directly affects the current–voltage properties of a semiconductor/metal junction.

#### 2.1.4 Trends in Contact Properties

The values of  $V_{bi}$  and  $\phi_b$  are key experimental quantities that are used to characterize the physical properties of semiconductor/metal interfaces. If  $V_{bi}$  or  $\phi_b$  can be determined, then  $W$ ,  $Q$ ,  $\mathcal{E}(x)$ , and most of the other important thermodynamic quantities that are relevant to the electrical properties of the semiconductor contact can be readily calculated using the simple equations that have been presented above. Methods to determine these important parameters can be found in the literature.<sup>2</sup> However, it would be useful at this point in the discussion to consider what values of  $\phi_b$  and  $V_{bi}$  are expected theoretically for a given semiconductor/metal interface. By definition,  $\phi_b = (E_{F,m} - E_{cb})/q$  at the electrode surface (Figure 4b). Thus, in principle, the barrier height can be predicted if the energies of the semiconductor band edges and the electrochemical potential of the metal can be determined with respect to a common reference energy.

In the literature, the work function of a metal,  $\phi$  (in eV), is often used to estimate the degree of charge transfer at semiconductor/metal junctions.<sup>12</sup> The work function of a metal is defined as the minimum potential experienced by an electron as it is removed from the metal into a vacuum. The work function  $\phi$  is often used in lieu of the electrochemical potential of a metal, because the electrochemical potential of a metal is difficult to determine experimentally, whereas  $\phi$  is readily accessible from vacuum photoemission data.<sup>12</sup> Additionally, the original model of semiconductor/metal contacts, advanced by Schottky, utilized differences in work functions, as opposed to differences in electrochemical potentials, to describe the electrical properties of semiconductor/metal interfaces.<sup>13</sup> A more positive work function for a metal (or more rigorously, a more positive Fermi level for a metal) would therefore be expected to produce a greater amount of charge transfer for an  $n$ -type semiconductor/metal contact.<sup>2</sup> Therefore, use of metals with a range of  $\phi$  (or  $E_{F,m}$ ) values should, in principle, allow control over the electrical properties of semiconductor/metal contacts.

To this point, we have restricted the specifics of our discussion to semiconductor/metal contacts. However, a

similar description of the interfacial equilibration process also applies to contacts between two dissimilar types of semiconductors. The most common form of these types of junctions is obtained when an  $n$ -type semiconductor is contacted with a semiconducting layer that has been doped  $p$ -type. When the two materials differ only in the type of doping, such junctions are called  $p$ – $n$  homojunctions. To control the electric field in the  $n$ -type semiconductor, the  $p$ -type semiconductor is usually highly doped. The conductivity, and capacitance, of the highly doped  $p$ -type phase is then much larger than that of the  $n$ -type phase. In this situation, the electrostatics of the  $p$ – $n$  homojunction closely resemble those of  $n$ -type semiconductor/metal contacts.

The biggest advantage of semiconductor homojunctions is the lack of a metallurgical junction between two structurally dissimilar solid phases. A homojunction provides an interface that is more perfect structurally, as well as less chemically reactive, than the junction between a semiconductor and a metal. Another advantage of a homojunction is that control over the Fermi level of the contacting phase is readily accomplished through changes in its dopant density. In contrast, for semiconductor/metal junctions, changing the Fermi level of the contacting phase requires a change in the nature of the metal, and thereby produces entirely new chemical interactions at the semiconductor interface. Because of their high electrical quality and ease of fabrication, homojunctions are used in a variety of technological applications in the semiconductor industry. The equations describing their performance are well-documented, and will not be described in more detail here.<sup>10,14</sup> However, the electrostatics of charge-transfer equilibration are readily obtained using slight modifications of the description presented above in equations (1–7).

A third type of semiconductor junction uses a conducting liquid to contact the semiconductor. Generally, the solvent and electrolyte do not participate in the charge-transfer process. Therefore, to control the Fermi level of the liquid phase, a donor/acceptor pair (a ‘redox couple’) must be added to the solution. The electrochemical potential, or Fermi level, of the solution phase is then given by the Nernst equation (equation 8):

$$E\left(\frac{A}{A^-}\right) = E^\circ\left(\frac{A}{A^-}\right) + \frac{RT}{eF} \ln \frac{A}{A^-} \quad (8)$$

where  $E^\circ(A/A^-)$  is the formal redox potential of the redox couple,  $[A]$  and  $[A^-]$  are the concentrations of the oxidized and reduced forms of the redox couple,  $R$  is the gas constant,  $F$  is Faraday’s constant, and  $e$  is the number of electrons per molecule oxidized or reduced in the reduction/oxidation process. The redox potential of the solution ( $E(A/A^-)$ ) is related to the electrochemical potential by  $E(A/A^-) = E(A/A^-)/q$ .

The electrostatics of charge transfer for semiconductor/liquid interfaces closely resemble those for semiconductor/metal contacts.<sup>15</sup> In the common experimental situation of

a liquid with a high concentration of a supporting electrolyte and with a significant concentration of electroactive reagents, the equilibrium electrochemical potential of the semiconductor/liquid contact is dictated by the initial electrochemical potential of the solution phase. This occurs because the liquid phase has a large capacity to accept charge with a minimal change in energy, in an analogous fashion to the metal portion of a semiconductor/metal contact. In addition, the significant capacitance of a liquid phase with a high concentration of supporting electrolyte dictates that essentially all of the voltage drop will occur in the semiconductor. This is also analogous to the situation for a semiconductor/metal contact. Under these conditions, equations (1–7) can therefore be directly applied to the electrostatic situation at a semiconductor/liquid contact, even though they were developed in our discussion during consideration of a semiconductor/metal contact.

As for semiconductor/metal contacts, a change in the Fermi level of the liquid phase should result in a different amount of charge transferred across the semiconductor/liquid junction. For semiconductor/liquid junctions, the important energetic trends for a series of different liquid contacts can thus be determined by measuring the solution redox potential relative to a standard reference electrode system. Within this model, solutions with more positive redox potentials should induce greater charge transfer in contact with *n*-type semiconductors.

Unfortunately, a problem arises when attempting to compare the electrochemical potential of the solution and the electrochemical potential of the semiconductor. Like most electronic energy levels for molecules, the Fermi level of the semiconductor is usually determined relative to the vacuum level. Experimental measurements to determine  $E_{F,sc}$  for semiconductors (generally through determination of the semiconductor work function and dopant density) yield values that can be related to the energy of an electron in vacuum.<sup>16</sup> However, electrochemical potentials of liquid phases can only be measured as potential differences between the test solution and a solution that is used as a reference.<sup>15</sup> Since it is not possible to measure directly the energy of an individual redox couple relative to the vacuum level, it is not possible to determine directly the desired relationship between the energy level on the solid side of the junction and that on the liquid side.

Typically, the reference level for the solution redox potential is chosen to be the normal hydrogen electrode (NHE). Some tabulations use the saturated calomel electrode (SCE) as the reference level with the difference between these two scales well-known to be  $NHE = -0.2412\text{ V}$  versus SCE.<sup>15</sup> The fundamental problem lies in the determination of the absolute energy of the NHE relative to vacuum. Although a method to determine directly the absolute electrochemical potential of an NHE has not yet been described, a recent indirect measurement has indicated that it is approximately 4.4 eV below the vacuum level.<sup>17,18</sup> This value is often used to relate the solution electrochemical potential scale to the solid electrochemical potential scale. It provides the best approximation that is presently available to calculate the

values of  $\phi_b$  and  $V_{bi}$  for semiconductor/liquid contacts, based only on the values of  $E_{cb}$  and  $E(A/A^-)$ .

## 2.2 Accumulation

We have described above the relevant physics and electrostatics for a depleted semiconductor/metal contact. It is also possible, however, that the initial electrochemical potential of the metal will be more negative than the Fermi level of the semiconductor. During the approach to equilibrium, electrons will then tend to flow into the semiconductor from the metallic phase. This flow of electrons into the semiconductor leads to a qualitatively different energetic situation at the semiconductor/metal junction relative to the situation in depletion. This situation is technologically desirable to form ohmic, electrically resistive contacts to semiconductors. We discuss the charge-transfer equilibration for these types of contacts in this section.

When electrons from the metallic phase are transferred into the *n*-type semiconductor, these electrons are not confined to dopant atom sites. Instead, the majority carriers exist as mobile charges in the conduction band. Because these excess majority carriers need not reside on dopant atoms, but can

**Figure 5** An energy diagram of a semiconductor/metal junction in accumulation. (a) Before charge equilibration occurs, the electrochemical potential of the semiconductor ( $E_{F,sc}$ ) is more positive than the Fermi level of metal ( $E_{F,m}$ ), and electrons will flow from the metal into the semiconductor. (b) After charge equilibration has occurred, an accumulation layer containing negative charges is formed in the semiconductor

also reside on lattice atoms of the semiconductor, the charge density that can be supported in accumulation is not limited by the dopant density. Instead, it is more closely approximated by the atom density in the crystal lattice. The spatial region in the semiconductor where the negative charges accumulate is called the accumulation region (Figure 5). The thickness of an accumulation region is therefore far smaller than that of a depletion region, for the same material and same amount of charge transferred across the interface. The width of an accumulation layer is typically less than  $100 \text{ \AA}$ ,<sup>19</sup> while the width of the depletion region is usually on the order of micrometers.<sup>1</sup>

Experimentally, the thin width of an accumulation layer implies that the electric potential gradient will not extend significantly into the semiconductor. The discussion in Section 3 will demonstrate that semiconductors in depletion act as rectifiers to current flow, selectively passing charge carriers in one direction while impeding their flow in the opposite direction. In accumulation, however, the lack of a significant barrier to charge flow implies that the semiconductor contact will be resistive, but not rectifying, to current flow. Thus, semiconductor/metal interfaces in accumulation are not useful for applications that require rectification. They are quite useful, however, for a variety of devices in which ohmic electrical contacts are required. They are also useful for basic investigations of the electrostatics of junction formation.<sup>20</sup>

### 2.3 Fermi Level Pinning

In discussing the behavior of semiconductor/metal junctions in depletion, it has been assumed that if the energy of the conduction band edge,  $E_{cb}$ , and the electrochemical potential of the contacting phase were known, their difference would yield a quantitative prediction of the barrier height for a given interface (Figure 4). Furthermore, even if the absolute magnitude of  $\phi_b$  is not known, it should still be the case that a change in the electrochemical potential of the contacting phase should yield a defined change in the barrier height, and also in the built-in voltage, of the resulting semiconductor junction. The scenario in which these conditions apply is often called the ‘ideal’ behavior of a semiconductor contact. However, for many semiconductor contacts, this ideal behavior is not observed experimentally. In fact, in some systems, especially semiconductor/metal contacts, changes in the electrochemical potential of the contacting phase do not yield *any* change in properties of the junction. In the remainder of this section we describe how this important class of exceptions to ideal behavior can be understood, and we also describe the implications of this nonideal junction behavior for chemical control of device properties.

The key experimental observation is that the built-in voltage in the semiconductor,  $V_{bi}$ , often does not change as the electrochemical potential of the contacting phase is varied.<sup>21</sup> Attaining equilibrium between two phases requires

that different degrees of interfacial charge transfer must occur when the initial electrochemical potential difference between these phases is changed. The experimental observation therefore indicates that another source or sink for charge must exist in the real interfacial system. These sources and sinks for charges are often referred to as surface states. Their ability to ‘buffer’ the semiconductor from changes in the electrochemical potential of the contacting phase is referred to as Fermi level pinning.

Surface states can arise simply because the atomic bonding at a semiconductor surface is necessarily different from that in the bulk. For example, in a Si lattice, the bonds at the Si surface are not fully coordinatively saturated. To relieve this unsaturation, either a surface reconstruction can occur and/or bonds to the metallic material can be formed. This distinct type of surface bonding results in a localized electronic structure for the surface which is different from that in the bulk. The energies of these localized surface orbitals are not restricted to reside in the bands of the bulk material, and can often be located at energies that are inside the band gap of the semiconductor. Orbitals that reside in this forbidden gap region are particularly important, because they will require modifications of our ideal model of charge equilibration at semiconductor/metal interfaces.<sup>12</sup>

To understand Fermi level pinning, we need to reconsider the charge equilibration process when the semiconductor/metal junction has a high density of surface states. As an example, we will consider a situation in which the surface states are half-filled when in equilibrium with a given metal and a semiconductor. The relevant question in this example concerns the change in  $V_{bi}$  when the electrochemical potential of the metal is made more positive. In the ideal model, the required charge had to be transferred by removing electrons from dopant atoms further into the semiconductor (Figure 2). As described above, this process required increases in both  $W$  and  $V_{bi}$ .

However, owing to the presence of occupied surface states, another source of charge is available in our nonideal system. If the charge required to equilibrate the junction is extracted from the surface states, and if the surface state density is sufficiently high to supply all of the required charges, then the junction can come to equilibrium without producing any change in  $V_{bi}$ . This situation occurs because no additional dopants have been ionized in the semiconductor. Instead, the additional charge is provided by the surface states. This situation is called Fermi level pinning; such terminology is used when the position of the semiconductor Fermi level is controlled by the occupancy of the surface states, as opposed to being controlled by the electrochemical potential of the metal.<sup>12</sup>

Quantitative calculations of the number of surface states that are needed to achieve Fermi level pinning will not be described here. However, such calculations show that even surface state densities as low as 10% of a monolayer ( $10^{14} \text{ states cm}^{-2}$ ) can provide sufficient charge to induce complete

Fermi pinning at semiconductor/metal contacts.<sup>21</sup> In other words, for a 1–2 V change in the work function of the metal, this density of surface states is sufficient that the values of  $W$  and  $V_{bi}$  will not change.

Lower surface state densities will, of course, produce less of a Fermi level pinning effect. This will result in an increased sensitivity of  $V_{bi}$  to changes in  $E_{F,m}$ . A quantitative measure of the degree of ideality of a junction can be obtained by plotting changes in  $V_{bi}$  (or  $\phi_b$ ) as a function of changes in  $E_{F,m}$ . Generally, however, as discussed above, values for  $E_{F,m}$  are not available, so the work function  $\varphi$  is used instead. When the slope of a plot of  $V_{bi}$  versus  $\varphi$  is 1.0, the ideal situation is attained. When the slope of such plots is  $\sim 0$ , complete Fermi level pinning is present. Intermediate situations, with  $0 < \text{slope} < 1.0$ , or nonlinear behavior of  $V_{bi}$  vs.  $\varphi$ , are often referred to as partial Fermi level pinning.<sup>1,12</sup>

Fermi level pinning is generally an undesirable feature of semiconductor contacts. Its presence implies that there is a lack of chemical control over the electric field strength in the semiconductor. Some reports have appeared in the literature describing the preparations of semiconductor surfaces with acceptably low levels of deleterious surface states.<sup>22</sup> In others, surface modification procedures have been explored with the aim of forming bonds to the defects to remove the surface states.<sup>23,24</sup> Such efforts are extremely important, as the problem of Fermi level pinning remains a key challenge to chemists interested in manipulating the properties of semiconductors.

### 3 CHARGE TRANSFER AT A SEMICONDUCTOR JUNCTION

Up to this point, we have considered the charge flow that occurs to produce the equilibrium state between a semiconductor and a contacting phase. This type of charge flow is a prerequisite for the use of semiconductor junctions in essentially any technological application. However, understanding this transient charge flow is not sufficient to describe the electrical properties of semiconductor junctions under steady state, nonequilibrium conditions. Ultimately, the steady-state current–voltage behavior is the practical characteristic that generally determines the figure of merit of a particular semiconductor device, and therefore determines its suitability for a particular application. For instance, excellent steady-state rectification is desired for energy conversion devices, photonic detectors, and some other devices, while ohmic contacts are necessary for most transistor applications as well as for various other devices.<sup>1</sup> Our goal in this section is to establish a framework for describing the current–voltage behavior of a given semiconductor contact, and to establish a basis for choosing a particular type of contact for a particular type of application.

#### 3.1 Current–voltage Behavior of a Semiconductor/metal Junction

In describing the steady-state current–voltage properties of semiconductor contacts, we will use, with no loss of generality,  $n$ -type semiconductor/metal contacts as our specific example for discussion. A balanced chemical equation that represents the interfacial charge transfer at a semiconductor/metal contact is

In equation (9), the forward reaction represents the transfer of electrons from the semiconductor into the contacting phase, and the reverse reaction represents the transfer of charge in the opposite direction. This equation, in combination with a simple kinetic model, can be used to obtain an expression for the current–voltage properties of a semiconductor contact.

In any chemical system, no net formation of products or net destruction of reactants occurs at equilibrium. There is, however, always some rate of conversion of an individual set of reactant molecules into a set of product molecules, and vice versa. At equilibrium, these rates cancel each other exactly. An analogous situation holds for charge transfer at a semiconductor/metal interface: at equilibrium, the rate of electrons flowing from the semiconductor into the metal must exactly equal the rate at which electrons flow into the semiconductor from the metal. Away from equilibrium, the rate constants for these processes will remain fixed for the interface of interest. However, the concentrations of the reactants and products will differ from their equilibrium values, and a net current can therefore be sustained through the interface. Our strategy in describing current flow is to evaluate the currents at equilibrium in accord with equation (9), and then to modify this treatment to include nonequilibrium conditions.

##### 3.1.1 Charge Transfer at Equilibrium

The simplest model of electron transfer across a semiconductor/metal interface assumes that the current depends linearly on the concentration of electrons at the semiconductor surface,  $n_s$ . It also assumes that the concentrations of acceptor and donor states in a metal are extremely large;<sup>9</sup> thus, these variables can be assumed to be constant and can be incorporated as time-independent quantities into the appropriate rate equations. This assumption is extremely reasonable for the moderate current densities that flow through typical semiconductor/metal interfaces.<sup>1</sup>

At a semiconductor/metal contact, the rate of direct electron transfer from an  $n$ -type semiconductor to the metal can therefore be expressed as

$$\text{rate of electron injection into the metal} = k_n n_s \quad (10)$$

where  $k_n$  is the rate constant for the electron transfer. This expression represents the rate law for the forward chemical rate, that is, it represents the rate of formation of products for the chemical reaction in equation (9).

To maintain equilibrium, there must also be a current in the opposite direction that opposes this forward rate, that is, electrons must also be able to leave the metal phase and enter the semiconductor conduction band. Because the electrons enter the empty states of the semiconductor, the concentration of these empty states can be taken as a constant. This leads to the expression

$$\text{rate of electron transfer from the metal} = k_n^{-1} \quad (11)$$

In equation (11),  $k_n^{-1}$  is the reverse reaction rate constant, and it is independent of  $n_s$ . The concentration of vacant states in the semiconductor and the concentration of filled states in the metal has been incorporated into the value of  $k_n^{-1}$ . This rate is called the reverse rate, because it represents the formation of the species on the left-hand side of the reaction represented in equation (9). At equilibrium (when  $n_s \equiv n_{so}$ ), these rates must be equal to each other ( $k_n^{-1} = k_n n_{so}$ ).

The net rate of electron transfer into the metal,  $-dn/dt$ , is always the forward rate minus the reverse rate. From equations (9–11), we then obtain the general relationships

$$-\frac{dn}{dt} = k_n n_s - k_n^{-1} \quad (12)$$

$$-\frac{dn}{dt} = k_n (n_s - n_{so}) \quad (13)$$

Equations (12) and (13) were obtained by treating charge transfer across a semiconductor/metal interface as we would treat any other simple chemical kinetics problem. It states that the net rate at which charge crosses the semiconductor/metal interface is the rate of product formation minus the rate of reactant formation. Although equation (13) is exactly equivalent to equation (12), the form that we have adopted for equation (13) will be extremely useful in deriving concise expressions for the current–voltage relationship of a semiconductor/metal contact. This is because equation (13) expresses the net rate of charge transfer relative to the situation at equilibrium, where no current flows across the interface. According to equation (13),  $-dn/dt = 0$  at equilibrium (as must be the case, because  $n_s = n_{so}$  by definition). Away from equilibrium,  $n_s \neq n_{so}$ , so charge will cross the interface, and thus  $-dn/dt \neq 0$ .

### 3.1.2 The Current–voltage Characteristics of a Junction

It is now a simple task to describe the interfacial current as a function of applied voltage. Since the current is merely the electron transfer rate multiplied by the charge on an electron and by the surface area of the electrode,  $A_s$ , the interfacial

electron transfer current can be written as:

$$I = -q A_s \left( -\frac{dn}{dt} \right) = -q A_s k_n (n_s - n_{so}) \quad (14)$$

In this notation, the current,  $I$ , is defined to be negative when electrons flow from the semiconductor to the metal. This notation is consistent with the electrochemical definition of a reduction current (electrons leaving the electrode). The dependence of the current on the applied voltage is implicit in  $n_s$ . To obtain this voltage dependence explicitly, we need to remember that the electron concentration at the surface of a semiconductor is related to the electron concentration in the bulk. As given in equation (7), the surface electron concentration at equilibrium is given by

$$n_{so} = n_b \exp \left( -\frac{q V_{bi}}{kT} \right) \quad (15)$$

Similarly, when a voltage  $V$  is applied across a semiconductor/metal junction, the total voltage drop in the semiconductor depletion region is  $V_{bi} + V$ , so we obtain an analogous Boltzmann relationship away from equilibrium:

$$n_s = n_b \exp \left[ -\frac{q(V_{bi} + V)}{kT} \right] \quad (16)$$

This equation represents the physical situation that the electron concentration at the semiconductor surface can be either increased or decreased through the use of an additional voltage. This applied voltage controls the surface carrier concentration in the same fashion as the built-in voltage, so the same Boltzmann relationship applies.

Substituting equations (15) and (16) into equation (14), we obtain the desired relationship between the current and the voltage of a semiconductor/metal junction:

$$I = -I_0 \left[ \exp \left( -\frac{qV}{kT} \right) - 1 \right] \quad (17)$$

where  $I_0 = q A_s k_n n_{so}$ .  $I_0$  is called the exchange current, because it is the value of the current that is present at equilibrium.  $I_0$  is responsible for transforming reactants into products, and vice versa, at a semiconductor/metal interface at equilibrium. For convenience,  $I_0$  is defined as a positive quantity.  $I_0$  is clearly dependent on the value of the equilibrium surface electron concentration, because a smaller exchange current should flow at equilibrium if there are fewer electrons available to exchange with a particular contacting phase.

We are now in a position to examine the properties of the current–voltage ( $I$ – $V$ ) behavior of a semiconductor/metal contact in detail. Equation (17) predicts that the current is exponentially dependent on the voltage for  $V < 0$ , but is independent of voltage, and of opposite sign, when  $V > 0$ . This can be understood qualitatively by reference to the elementary rate processes that result from equations (12)

and (13). The net current across the semiconductor/metal interface is always given by the difference of the forward and reverse interfacial charge transfer rates, that is, by the rate of the reaction going to the right minus the rate going to the left, as written in equation (12). For voltages that reduce the surface electron concentration below its equilibrium value, Le Chatelier's principle implies that the reaction should proceed to the left as written in equation (9). Physically, a value of  $V > 0$  will yield a larger electric potential drop in the semiconductor, which will exponentially reduce the surface concentration of electrons. This lower surface electron concentration will reduce the rate of electrons leaving the semiconductor (Figure 6a). However, the rate of electrons

entering the semiconductor, that is, the rate of reactant formation, will remain unchanged. Therefore, for this direction of voltage change, the net current will be independent of voltage. This direction of the applied voltage is called reverse bias. In reverse bias, the reaction proceeds to the left as written in equation (9), and electrons are injected into the semiconductor from the metal.

For voltages that increase the surface electron concentration above its equilibrium value ( $V < 0$ ), the sign of the current will be opposite to that of the current obtained at reverse bias. Le Chatelier's principle now implies that the reaction will go to the right as written in equation (9), so there will be a net transfer of electrons to the metal phase. Through the Boltzmann relationship, in forward bias ( $V < 0$  for our *n*-type semiconductor example) the surface concentration of electrons increases exponentially with increased bias. This increased concentration of reactants results in an exponential increase in the forward rate of interfacial charge transfer, but has no effect on the reverse rate of charge transfer (Figure 6b). Because the rate of electrons leaving the semiconductor at high forward bias dominates the rate at which they enter it, the net current will depend exponentially on the applied voltage (specifically, when  $\exp(-qV/kT) \gg 1$ ), as indicated by equation (17).

The current–voltage characteristic described by equation (17), where the current can flow predominantly in only one direction under an applied potential, is called rectification. The rectification characteristic is typical of electrical diodes.<sup>1</sup> Equations that have the form of equation (17) are therefore generally called diode equations. We have shown that a semiconductor/metal interface is expected to obey the diode equation when interfacial electron transfer is the rate-determining step for charge movement. In this situation, the applied voltage changes the electron concentration at the interface of the semiconductor, and this is directly reflected in the current versus voltage relationship of a semiconductor/metal interface (Figure 7). This behavior is a direct result of the Boltzmann relationships of equations (15) and (16).

Up to this point, there has been no explicit discussion of the role of the metal phase in the current–voltage behavior. For ideal semiconductor/metal junctions, it is relatively straightforward to evaluate  $I_0$  in terms of the thermodynamic properties of the metal contact. Referring to equations (12–17), knowledge of either  $k_n$  or  $k_n^{-1}$  is sufficient to fully describe  $I_0$ . It is intuitively easier to appreciate the quantities incorporated into  $k_n^{-1}$ , which represents the rate constant for injection of electrons from the metal into the semiconductor. This charge-transfer process can be broken down conceptually into two steps. First, electrons in the metal must overcome the activation energy to enter the conduction band of the semiconductor. Because the highest occupied state in the metal is at the Fermi level,  $E_{F,m}$ , and the lowest unoccupied state at the semiconductor surface has an energy of  $E_{cb}$ , the electron transfer process will have an activation energy of  $E_{F,m} - E_{cb} = q\phi_b$ . Using a simple Arrhenius treatment of

**Figure 6** An energy diagram of the charge-transfer process at an *n*-type semiconductor/metal interface when an external potential ( $V$ ) is applied across the semiconductor electrode. The applied potential changes the electric potential difference between the semiconductor surface and the bulk region. This perturbs the concentration of electrons at the surface of the semiconductor ( $n_s$ ), and a net current flows through the semiconductor/metal interface. The forward reaction represents the transfer of electrons from the semiconductor to the metal and the reverse reaction represents the injection of electrons into the semiconductor from the metal. The width of the arrows indicates schematically the relative magnitude of the current. (a) The reverse bias condition for an *n*-type semiconductor ( $V > 0$ ). The forward reaction rate is reduced relative to its equilibrium value, while the reverse reaction rate remains constant. A net positive current exists at the electrode surface. (b) The forward bias condition ( $V < 0$ ), the forward reaction rate increases compared to its equilibrium value, while the reverse reaction rate remains unaffected. A net negative current exists at the electrode surface

**Figure 7** The current–voltage ( $I$ – $V$ ) behavior of an  $n$ -type semiconductor/metal junction in the dark. The shape of the  $I$ – $V$  curve is described by the diode equation (equation 17); thus, such a curve is referred to as a diode curve. The difference between curves 1 and 2 is that the equilibrium exchange current,  $I_0$ , is greater for curve 2

this rate constant,<sup>25</sup>  $I_0$  can therefore be written as

$$I_0 = q A_s k_n^{-1} = \text{constant} \times \exp\left(-\frac{q\phi_b}{kT}\right) \quad (18)$$

In the second conceptual step of this process, electrons with the appropriate energy must actually cross the semiconductor/metal interface, as opposed to thermalizing and remaining in the metal. A chemical analog of this event is that, once a set of reactants reaches the transition state, there is a defined probability that the reagents will proceed to form products, as opposed to reverting back to reactants. The constant in equation (18) therefore contains the probability of an actual interfacial charge transfer event. This constant also includes parameters that describe the maximum frequency for electron transfer events at the particular semiconductor/metal interface under consideration. Taken together, these two quantities closely resemble the preexponential factor in an Eyring rate expression for a chemical reaction.<sup>25</sup>

For a semiconductor/metal contact, it can be shown that the constant in equation (18) has a weak temperature dependence, that is,  $\text{constant} \propto T^2$ .<sup>1</sup> This temperature dependence is generally written explicitly in the expression for  $I_0$ , so the conventional form of the exchange current for a semiconductor/metal contact is

$$I_0 = A_s A^{**} T^2 \exp\left(-\frac{q\phi_b}{kT}\right) \quad (19)$$

where  $A_s$  is the area of the contact, and  $A^{**}$  is the effective Richardson constant. The constant  $A^{**}$  typically has a value of

$10^2 \text{ A cm}^{-2} \text{ K}^{-2}$ .<sup>1</sup> The value of  $A^{**}$  is dependent on the type of semiconductor and type of metal at the particular contact of interest, but fortunately the values of  $A^{**}$  for common  $n$ -type semiconductor/metal contacts are relatively constant.<sup>1,2</sup> The major factor that determines the magnitude of  $I_0$  is clearly the exponential term, which depends on the barrier height of the contact.

The role of  $E_{F,m}$  in determining the electrical properties of a semiconductor/metal contact is now obvious. Physically, a more positive electrochemical potential of the metal will produce a larger barrier height and, according to equation (19), will produce a larger activation energy for electron transfer. This will produce a smaller exchange current at the semiconductor/metal contact. This effect on the exchange current can also be seen by considering the influence of  $E_{F,m}$  on the semiconductor phase. In the semiconductor, a larger value of  $\phi_b$  will produce a larger built-in voltage at an  $n$ -type semiconductor/metal interface (see Figures 2 and 4). This increased band bending decreases the equilibrium electron concentration at the surface ( $n_{so}$ ), and leads to a smaller exchange current for this semiconductor/metal junction. Control over  $\phi_b$  therefore produces control over  $I_0$ , and thus produces control over the rectification properties of semiconductor/metal contacts.

The rectification properties of semiconductor interfaces are the most important electrical characteristic of semiconductor contacts. Certain types of devices, such as transistors, require both ohmic and rectifying contacts on a given semiconductor surface, whereas other devices, such as Schottky barriers, are based on the inherent rectification properties of semiconductor/metal junctions. Numerous photonic devices, such as photon detectors and photovoltaic cells, require rectification at a semiconductor junction, and light-emitting diodes require both ohmic contacts and rectifying junctions in a well-defined geometry. Thus, successful fabrication of a desired device structure depends entirely on the electrical properties of the specific semiconductor contacts that are formed in the process. The principles described above allow the rational fabrication of contacts with the desired properties, and also describe the operation of the resulting devices within a simple, chemically intuitive, kinetic framework.

Although the discussion to this point has specifically focused on semiconductor/metal contacts, an identical formalism and analogous rate equations can also be used to describe the electrical properties of semiconductor/liquid contacts. Again the important factor is control over  $I_0$ , and again the energetic properties of the interface are the key factors that control the rectification properties of the system. In a semiconductor/liquid junction, it is the difference between the electrochemical potential of the solution and the energy of the conduction band edge ( $E(A/A^-) - E_{cb}$ ) which defines the barrier height energy of the system.

For liquids, the only major difference in the kinetic equations lies in the analog of the Richardson constant. The probability of interfacial charge transfer at a semiconductor/liquid

interface clearly depends on the chemical nature of the donor/acceptor pair that participates in the electron transfer event. For semiconductor/liquid contacts the exchange current is typically written as  $I_0 = A_s[A]n_{so}k_{et}$ , where  $A_s$  is the area of the contact,  $[A]$  is the concentration of the acceptor in the solution and  $k_{et}$  is the intrinsic rate constant for electron transfer at the semiconductor/liquid interface of interest.<sup>19</sup> The electron transfer rate constant is a very important parameter in the kinetics of electron transfer at a semiconductor/liquid junction, and  $k_{et}$  appears in most of the equations that utilize kinetic models for  $I_0$ . Theoretical expressions for  $k_{et}$  have been derived by Morrison and by Gerischer.<sup>19,26,27</sup> These treatments have been reviewed extensively in the literature, and are primarily based on the Marcus theory for electron transfer at metal electrodes.<sup>7,28–30</sup>

The interfacial kinetics processes at semiconductor/liquid contacts for reactions with one-electron, outer-sphere, redox species can be understood in a conventional theoretical framework. The rate constant  $k_n$  can be broken down into a term representing the attempt frequency,  $\nu_n$ , a term representing the electronic coupling between the electrons in the conduction band of the semiconductor and the redox acceptor state,  $\kappa_{el}$ , and a term representing the nuclear reorganization energy in the transition state from reactants to products,  $\kappa_n$ .<sup>29</sup> For outer-sphere electron transfer processes, the nuclear term is well-known to be:

$$\kappa_n = \exp \left[ \frac{(-E_{cb} - qE'(A/A^-) + \lambda)^2}{4\lambda kT} \right] \quad (20)$$

where  $\lambda$  is the nuclear reorganization energy.<sup>29</sup> The attempt frequency,  $\nu_n$ , is generally on the order of  $10^{13} \text{ s}^{-1}$ , being related to the vibrational frequency of the nuclear motions that drive the reaction to the transitional state. For a random distribution of nonadsorbing outer sphere acceptors in the solution, the electronic term,  $\kappa_{el}$ , theoretically has a value on the order of  $10^{-31} \text{ cm}^4$ .<sup>31</sup> Hence the theoretical maximum interfacial charge transfer rate constant for a nonadsorbing, weakly coupled outer-sphere redox system to a semiconductor is expected to be on the order of  $10^{-17} \text{ cm}^4 \text{ s}^{-1}$ . An alternative evaluation, using a Fermi Golden Rule approach to evaluate the maximum value expected for  $k_{et}$ , yields a similar value.<sup>32</sup>

Recent experimental studies have confirmed these theoretical expectations for several exemplary semiconductor/liquid interfaces.<sup>31</sup> Detailed rate measurements on  $n$ -Si/CH<sub>3</sub>OH-viologen<sup>2+/+</sup> and  $n$ -InP/CH<sub>3</sub>OH interfaces have validated the dependence of  $k_n$  on driving force, as predicted by equation (20), and have indicated that the value of  $k_n$  at optimal exoergicity is approximately  $10^{-17} \text{ cm}^4 \text{ s}^{-1}$ . Scanning electrochemical microscopy measurements of the kinetics at  $p$ -WSe<sub>2</sub>/H<sub>2</sub>O-Ru(NH<sub>3</sub>)<sup>63+/2+</sup> interfaces have yielded an interfacial charge-transfer rate constant of  $5.7 \times 10^{-17} \text{ cm}^4 \text{ s}^{-1}$ , and estimates of the nuclear terms for this reaction result in a rate constant at optimal exoergicity of  $2 \times 10^{-16} \text{ cm}^4 \text{ s}^{-1}$ .

Hence it appears that these types of processes seem to be reasonably well-understood both experimentally and theoretically. In contrast, inner-sphere electron transfer processes, and processes involving adsorbed redox species, are not well-understood at present.

Even for inner sphere processes and adsorbed species, owing to the dependence of  $n_s$  on barrier height, for an  $n$ -type semiconductor, more positive redox potentials generally yield smaller values of  $I_0$ , and produce highly rectifying behavior.

The electrical behavior of semiconductor/liquid contacts is thus very similar to that of semiconductor/metal contacts. For an  $n$ -type semiconductor, more positive redox potentials will yield smaller values of  $I_0$ , and will produce highly rectifying diode behavior. In contrast, more negative redox potentials will yield larger values of  $I_0$ , and will produce poorly rectifying diode behavior. Thus, one goal in constructing semiconductor/liquid junctions is to insure that chemical control is maintained over the  $I$ – $V$  properties of semiconductor/liquid contacts. Changes in the solution redox potential are therefore one of the most important methods of manipulating the  $I$ – $V$  properties of semiconductor/liquid interfaces.

Similar behavior is also obtained for semiconductor/semiconductor interfaces. For homojunctions, the interfacial energetics are fixed by the nature of the solid, but the degree of charge transfer, and therefore the degree of rectification, is determined by the doping levels of each portion of the semiconductor device. In this situation,  $I_0$  is a function of the dopant density of each phase. For such devices,  $I_0$  is also a function of other physical properties of the material, such as the lifetime and diffusion coefficients of the charge carriers in the sample of interest. The particular equations that govern the current–voltage properties of homojunctions are well-known in the solid-state physics literature and will not be discussed in detail here.<sup>1</sup> However the fundamental operating principles of these types of devices are also readily grasped by application of the equations discussed above.

Although the diode behavior of a semiconductor/metal and a semiconductor/liquid junction have been derived by assuming that electron transfer is the important charge flow process across the interface, the diode equation is generally applicable to semiconductor/contact devices even when other processes are rate limiting, as is often the case for semiconductor/liquid junctions. A similar derivation can be performed for other possible charge flow mechanisms, such as recombination of carriers at the surface and/or in the bulk of the semiconductor. It can be shown that the  $I$ – $V$  relationships for these mechanisms almost all adopt the form of equation (17).<sup>2,6</sup> The major difference between the various mechanisms is the value of  $I_0$  for each system. Mechanistic studies of semiconductor junctions therefore generally reduce to investigations of the various factors that control  $I_0$ . Such studies also involve quantitative comparisons of the magnitude of  $I_0$  with the value expected for a specific charge transport mechanism. These types of investigations

have yielded a detailed level of understanding of many semiconductor interfaces. Recent reviews, describing more details of this work on semiconductor/liquid interfaces, have been written by Koval<sup>7</sup> and by Lewis.<sup>30,31</sup> However, regardless of mechanism, the key point is that chemical control over  $I_0$ , and over the rectification properties of semiconductor contacts, is the ultimate goal of semiconductor contact chemistry.

#### 4 SUMMARY

Using a very simple, qualitative approach, the fundamental properties of semiconductor contacts that are responsible for the operation of rectifiers, transistors, photovoltaic devices, and light-emitting diodes have been described. The charge-transfer processes across semiconductor interfaces are ultimately responsible for this behavior; thus, control over the interfacial charge-transfer reactions is crucial to control over the properties of semiconductor contacts. The penetration of the electric field and the electric potential into a bulk semiconductor phase yields a nonuniform carrier concentration in the sample, and produces contacts that either attract or repel specific types of charge carriers. Chemical control over these electric fields is crucial to the technology of semiconductor contacts. In principle, such control can be established through a simple variation in the electrochemical potential of the contacting phase. In practice, this ideal model often does not apply, and other factors influence or completely determine the interfacial electric field strength. The basis for semiconductor contact chemistry can, however, be understood in a straightforward fashion once the nature of the interface is successfully elucidated. These principles can be applied in a quite general fashion to semiconductor/semiconductor, semiconductor/metal, semiconductor/liquid and semiconductor/polymer contacts, making the approach valuable for understanding the operational principles of a variety of technologically important semiconductor devices.

## Glossary

*Absorption coefficient:* a parameter that characterizes the ability of a solid to absorb light of a given wavelength

*Acceptor:* an impurity that scavenges an electron from the semiconductor; acceptors produce a hole in the valence band and a negative charge on the dopant atom

*Charge carrier:* either an electron or a hole, both of which are capable of conducting electrical charge in a semiconductor

*Common anion rule:* a general guideline, which states that the lattice anion controls the position of the valence band edge of a semiconductor

*Conduction band:* the lowest unfilled energy band in a solid

*Conduction band edge:* the bottom of the lowest unfilled energy band in a solid

*Deep dopant:* a dopant whose energy level is close to the middle of the semiconductor band gap

*Direct band gap semiconductors:* semiconductors that display a fully allowed electronic transition between the valence and conduction bands

*Donor:* an impurity that is readily ionized to produce an electron in the conduction band and a positive charge on the dopant atom

*Dopant atoms:* chemical impurities that are deliberately introduced into the semiconductor lattice to provide control over the conductivity and Fermi level of the solid

*Doping:* the introduction of specific chemical impurities into a semiconductor lattice to control the conductivity and the Fermi level of the semiconductor

*Effective density of states:* the number of electronic states within  $3kT$  of the edge of an energy band, where  $k$  is the Boltzmann constant and  $T$  is the temperature

*Energy bands:* a cluster of orbitals in which the individual molecular orbitals are packed closely together to form an almost continuous distribution of energy levels

*Fermi level:* the energy level at which the probability of finding an electron is 1/2. This quantity characterizes the tendency of a semiconductor to transfer charges to other phases

*Hole:* an electronic vacancy in the valence band of a solid

*Indirect band gap semiconductors:* semiconductors in which the lowest energy electronic transition between the valence and conduction bands is formally optically forbidden

*Intrinsic semiconductor:* an undoped semiconductor

*Majority carrier:* the predominant charge carrier in the bulk of a doped semiconductor

*Minority carrier:* the less abundant charge carrier in the bulk of a doped semiconductor

*n-type semiconductor:* a semiconductor sample, doped with donors, that has an excess of free electrons relative to the intrinsic sample

*Optical penetration depth:* the distance into the semiconductor at which the transmitted light intensity reaches  $1/e$  of the incident light intensity at the surface of the semiconductor

*p-type semiconductor:* a semiconductor sample, doped with acceptors, that has an excess of free holes relative to the intrinsic sample

*Semiconductor band gap:* the energy difference between the top of the valence band and the bottom of the conduction band in a semiconductor

*Shallow dopant:* a dopant whose energy level is close to either the valence band or the conduction band

*Valence band:* the highest filled energy band in a solid

*Valence band edge:* the top of the highest filled energy band in a solid

## 1 INTRODUCTION

Semiconductors constitute one of the most important classes of materials of the twentieth century. Their unique optical, electronic, and thermal properties make them well-suited for a variety of applications in the modern electronics industry. Semiconductors are of increasing interest to chemists owing to their applications in solar energy conversion,<sup>1–5</sup> organic synthesis,<sup>6,7</sup> and waste water treatment.<sup>8,9</sup> Common semiconductors can be formed from a variety of starting materials. Si and Ge are elemental semiconductors, whereas other semiconductors may be binary compounds (e.g. GaAs, CdS, and TiO<sub>2</sub>), ternary compounds (e.g. Hg<sub>0.2</sub>Cd<sub>0.8</sub>Te and Ga<sub>0.8</sub>As<sub>0.2</sub>P), or quaternary materials (e.g. In<sub>0.2</sub>Ga<sub>0.8</sub>As<sub>0.7</sub>P<sub>0.3</sub>) (see *Compound Semiconductor*). The unifying characteristic of semiconductors is their level of electrical conductivity. A semiconductor is generally defined as a material that has an electrical conductivity,  $\sigma$ , between  $10^{-9}$  ohm<sup>-1</sup> cm<sup>-1</sup> and  $10^2$  ohm<sup>-1</sup> cm<sup>-1</sup>.<sup>10</sup> Thus, semiconductors comprise the class of materials whose electrical conductivities are higher than those of insulators and lower than those of metals. Another, more useful experimental definition is that the conductivity of a semiconductor increases exponentially with increasing temperature. As described below, the conductivity of a semiconductor is ultimately determined by its chemical and electronic structure. The focus of this chapter is to describe the important chemical structures, optical characteristics, and electrical properties of semiconducting solids.

The conductivity of semiconductors can be deliberately manipulated through the introduction of specific chemical impurities. This process is known as doping. These chemical impurities, or dopants, can either donate additional charges to the semiconductor, or can accept charges from the solid. The introduction of dopants can greatly modify the electrical properties of semiconductors. In fact, in some cases, doping can effect changes of over eight orders of magnitude in the electrical conductivity of a semiconductor!<sup>11</sup> The factors involved in the choice of a particular dopant, and understanding the behavior of different dopant atoms in semiconductors, are two other chemical issues that will be discussed in this chapter.

Another important characteristic of semiconductors is their optical absorption properties. The optical properties of semiconductors are crucial to their uses as photovoltaic energy conversion devices, photonic detectors, light-emitting diodes, solid state lasers, and optical switches<sup>11</sup> (see *Semiconductor Interfaces*). Some semiconductors absorb both visible and ultraviolet light, while others only absorb photons in the

near-ultraviolet portion of the electromagnetic spectrum. The thickness of material required to absorb photons effectively can also vary widely in semiconductors, with strong absorbers requiring as little as 100 Å of material and weak absorbers requiring as much as 0.1 cm of material. The important optical properties of a semiconductor can also be understood from their chemical and electronic properties. Thus, a final goal of this chapter is to elucidate the chemical basis of the optical characteristics of semiconducting solids.

## 2 CRYSTAL STRUCTURES OF SELECTED SEMICONDUCTORS

To discuss the properties of semiconductors from a chemical perspective, it is important to first understand the structures of semiconducting solids. Semiconductors comprise a diverse group of inorganic materials and exhibit a variety of different *Crystal Structures*. The most basic semiconductor structure is based on the interpenetration of two face-centered cubic (fcc) lattices. A familiar, nonsemiconducting solid that adopts this structure is NaCl, where the Na<sup>+</sup> cations constitute one fcc lattice and the Cl<sup>-</sup> anions constitute the other (Figure 1(a)). Many specific crystal structures of semiconductors are related to this basic face-centered cubic lattice.

Covalent semiconductors, such as the elemental semiconductors Si and Ge, have structures in which the atoms achieve maximum bonding between nearest neighbor atoms. For Si and Ge, each atom prefers sp<sup>3</sup>-based tetrahedral bonding. Thus, these atoms will prefer a lattice in which tetrahedrally bonded atoms are positioned as closely as possible within the face-centered cubic structure. Si and Ge therefore adopt the cubic diamond lattice, in which half of the tetrahedral positions in the face-centered cubic lattice are filled with atoms (Figure 1(b)). A related structure is adopted by covalent, binary semiconducting solids having elements of similar electronegativities. For example, GaAs adopts the zinc blende structure, which is simply the cubic diamond structure with adjacent atoms throughout the structure alternating in type (Figure 1(c)). InAs, InP, and GaP are other examples of common covalent binary semiconductors that adopt the zinc blende structure.

In certain cases, when the semiconductor is composed of elements with very different radii and electronegativities, the lattice site in the tetrahedral position of a face-centered cubic structure becomes too small to accommodate one of the ions in the semiconductor. To maintain a lattice with a 1:1 cation:anion stoichiometry, the solid adopts a structure in which the atoms are instead hexagonally close-packed. As in the zinc blende structure, only half of the possible tetrahedral sites in this hexagonal structure are filled with atoms. This arrangement, which is adopted by semiconductors such as ZnO and CdSe (Figure 1(d)), is called the wurtzite structure.

**Figure 1** Structures of some common crystal lattices: (a) NaCl, (b) Si, (c) GaAs, (d) ZnO wurtzite, (e) TiO<sub>2</sub> rutile, (f) TiO<sub>2</sub> anatase, (g) MoS<sub>2</sub>. For the binary materials, the shaded circles represent the more electronegative elements (i.e. Cl, As, O, and S) and the empty circles represent the less electronegative elements (i.e. Na, Ga, Zn, Ti, and Mo)

Some materials, such as ZnS, can be found in either the zinc blende or the wurtzite structure. Comparison between these lattices shows that the wurtzite structure is more open, and the bonding more ionic, than is the zinc blende structure.

Taken together, these three structures (cubic diamond, zinc blende, and wurtzite) encompass the majority of the common semiconductor materials in use today. These structures, which share the common feature of having an average of four valence electrons per atom, are called *adamantine solids*.<sup>12</sup>

In several semiconducting solids, steric, or electronic factors can result in the adoption of nonadamantine structures. Semiconductors that adopt nonadamantine structures include metal oxides such as TiO<sub>2</sub> and SrTiO<sub>3</sub>, and transition metal dichalcogenides such as MoS<sub>2</sub>, WS<sub>2</sub>, and WSe<sub>2</sub>. TiO<sub>2</sub>, an important semiconductor, occurs in three forms: brookite, rutile, and anatase, but only rutile and anatase are commonly used.<sup>2</sup> Figures 1(e),(f) show the structures of the two common forms of TiO<sub>2</sub>. The rutile lattice is derived from a body-centered cubic structure, where one-half of the trigonal-planar sites are occupied by anions to maintain a 1:2 cation:anion stoichiometry. The anatase lattice is derived from the NaCl structure with only one-half of the sites in one fcc lattice occupied by the Ti<sup>4+</sup> cations. To date, large single crystals of TiO<sub>2</sub> have only been prepared in the rutile structure, while TiO<sub>2</sub> powders commonly contain both anatase and rutile components.<sup>2</sup>

Figure 1(g) illustrates a structure that is commonly found for transition metal dichalcogenide compounds such as MoS<sub>2</sub>, WS<sub>2</sub>, and WSe<sub>2</sub>. These semiconductors adopt a layered structure in which the transition metal is 'sandwiched' between two layers of chalcogenide atoms. This arrangement produces a van der Waals structure, because there is no covalent bonding between adjacent chalcogenide layers. A useful feature of this structure is that the weak interactions between these planes allow high quality surfaces of van der Waals crystals to be prepared merely by peeling layers of the crystalline sample apart, as opposed to the extensive chemical and/or mechanical etching procedures that are required to produce desired surfaces in the more covalent semiconductor structures.

The surface properties of semiconductors often depend on the nature of the exposed crystal face. By convention, the orientation of a semiconductor surface is defined by the crystal plane that lies perpendicular to the normal of the surface. The conventional notation for this plane is obtained using Miller indices.<sup>10,13</sup> First, it is necessary to identify the intercepts of the surface plane with the crystallographic axes. The reciprocals of these intercepts are then reduced to Miller indices, which are integers that have the same ratios as the reciprocals themselves. For example, the plane ABCD in Figure 2 has formal intercepts of  $\{1, \infty, \infty\}$  on the axes; thus, in the Miller index notation it is designated as the  $(1/1, 1/\infty, 1/\infty)$ , or  $(100)$  plane. When a plane has a negative axis intercept, a bar is placed over the corresponding Miller index. For example, the plane that intercepts the axes at  $x = -1$ ,  $y = \infty$ ,  $z = \infty$  would be designated as the  $(\bar{1}00)$  plane.

**Figure 2** A schematic representation of Miller indices, imposed upon the Si crystal lattice. The  $x$ -,  $y$ -, and  $z$ -axes are indicated on the Si lattice, with the Si (100) face shaded

In the Miller index notation, the convention for denoting a direction perpendicular to a particular plane is to put square brackets around the numbers denoting that plane. The  $x$ -axis in Figure 2, for instance, is the  $[100]$  direction.

In some structures, several planes and directions may be equivalent by symmetry. For example, this is the case for the (100), (010), (001),  $(\bar{1}00)$ ,  $(0\bar{1}0)$ , and  $(00\bar{1})$  planes in the diamond cubic structure. Equivalent directions are denoted concisely as a group by using angular brackets. Thus, the (100) directions in a diamond cubic lattice include all of the directions that are perpendicular to the six planes noted above. The Miller index notation thus provides a concise designation for describing the surfaces of semiconductor crystals.

### 3 BAND STRUCTURE AND OPTICAL PROPERTIES OF SEMICONDUCTORS

The structure of semiconducting solids provides a convenient basis for understanding the important electronic properties of these materials. The important optical and electrical characteristics of semiconducting solids arise from the delocalized electronic properties of these materials. To understand the origin of this electronic delocalization, we must consider the nature of the bonding within semiconductor crystals. The basic model that has been successfully used to describe the electronic structure of semiconductors is derived from the *Band Theory* of solids. Our treatment of band theory will be qualitative, and the interested reader is encouraged to supplement our discussion with the excellent reviews by

Hoffmann,<sup>14–16</sup> and with the classic texts by Ashcroft and Mermin,<sup>17</sup> Harrison,<sup>18</sup> Kittel,<sup>10,19</sup> Seitz,<sup>20</sup> and Goodstein.<sup>21</sup>

#### 3.1 Molecular Orbital Description of Semiconducting Solids

The process of obtaining delocalized molecular orbitals for solids is similar to the approach that chemists use to describe the bonding in simple diatomic molecules. However, when orbital theory is used to describe the electronic properties of a collection of atoms within a solid lattice, a different terminology is generally used. The process is first illustrated on a chemically familiar system consisting of polyenes of varying chain lengths. This methodology is then generalized to include the bonding description of inorganic semiconducting solids.

##### 3.1.1 Band Structure in Linear Conjugated Polyenes

An orbital description of the bonding in ethylene, which is the repeating unit in a straight chain polyene, is described first. In the Hückel molecular orbital (MO) description of ethylene (*see Hückel Theory*), the carbon atoms are  $sp^2$  hybridized into a  $\sigma$ -orbital framework. The remaining carbon p-orbitals interact to yield two orbitals of  $\pi$ -symmetry, one of which is bonding and the other antibonding with respect to the C–C interaction. This situation is qualitatively represented in Figure 3. In the ground state of ethylene, the bonding  $\pi$ -orbital is occupied by two electrons, and this orbital is lower in energy than the empty antibonding orbital. A discrete optical transition exists between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of ethylene, because a well-defined energy gap separates these two orbitals (*see HOMO–LUMO Gap*).

**Figure 3** The development of a polyene band structure from the molecular orbitals (MOs) of ethylene.<sup>14,15</sup> From left to right, the molecular orbitals progressively develop into a band structure as the length of the conjugated chain is increased. For shorter polyene chains,  $\Delta$  represents the HOMO–LUMO gap. For the infinite polyene chain, vb and cb denote the valence band and the conduction band, respectively, and  $E_g$  is the band gap

As the basic ethylene units are coupled together to form a larger molecule, the  $\pi$ -bonding will become more delocalized, and more atomic orbitals must be included in the overall molecular orbital description (Figure 3). When an infinite one-dimensional polyene chain is formed, it will contain an infinite number of bonding and antibonding molecular orbitals. In this infinite chain, the bonding orbitals will tend to cluster together into a tightly packed group, while the antibonding orbitals will cluster into another tightly packed group. It can be shown that these orbital clusters are separated by a well-defined HOMO–LUMO energy gap, just as in the cases of ethylene, 1,3-butadiene, 1,3,5-hexatriene, and other molecular oligomers that are precursors to the infinite chain polyene (Figure 3).<sup>14,15</sup>

Because the fully developed polyene has an extremely large number of molecular orbitals, a description of the  $\pi$ -bonding in this molecule can be simplified by considering groups of orbitals together as sets. Even though each of the molecular orbital distributions in the polyene consists of a large number of orbitals that are packed tightly together into a finite energy interval, we can ignore the energy spacing between the individual orbitals for most purposes. We can therefore consider the orbitals to form ‘continuous’ bands of energy levels (*see Energy Bands*). A shorthand notation for this assumption is to draw each band as a single block in energy. In this notation, there is an implicit understanding that there are actually a large number of states clustered together within this block (Figure 3). Under this scheme, the HOMO–LUMO gap is called the *Band Gap*.

### 3.1.2 Band Structure in Semiconducting Crystals

The band structure of a three-dimensional solid, such as a semiconductor crystal, can be obtained in a similar fashion to that of a polyene. Localized molecular orbitals are constructed based on an appropriate set of valence atomic orbitals, and the effects of delocalization are then incorporated into the molecular orbital as the number of repeat units in the crystal lattice is increased to infinity. This process is widely known to the chemical community as extended Hückel theory (*see Extended Hückel Molecular Orbital Theory*). It is also called tight binding theory by physicists who apply these methods to calculate the band structures of semiconducting and metallic solids.

We will not describe this process in detail for semiconducting solids, because there are complications that result from the different symmetry types of various unit cells, as well as from spin–orbit coupling considerations. These factors tend to increase the complexity of the MO description of inorganic solids relative to the simple MO treatment of polyenes. However, the principles of the procedure are the same as those outlined for the polyene example, with each individual atom in the lattice contributing a set of atomic orbitals toward the formation of crystal orbitals. These crystal orbitals will extend throughout the solid, and will yield discrete energy bands

when represented on an energy diagram, just as in our polyene example (Figure 4). By definition, the highest filled band is called the valence band of the semiconductor. Similarly, the lowest unfilled band is called the conduction band. Thus, we obtain energy diagrams for semiconductor crystals that are similar to the one presented in Figure 3 for the organic polyenes, with bands of orbitals representing the HOMO and LUMO for the material of concern (Figure 4).

In semiconductor terminology, the top of the valence band and the bottom of the conduction band are called the valence band edge and the conduction band edge, respectively. The energy of the conduction band edge is denoted as  $E_{cb}$ ; similarly, the energy of the valence band edge is denoted as  $E_{vb}$ . The energy difference between these levels is called the semiconductor band gap. The size of this band gap,  $E_g$ , is perhaps the most important characteristic of a semiconducting solid, as it influences many electronic properties of semiconductors. In general, semiconducting solids have band gaps that range from 0.5 to 3.5 eV; Table 1 lists the values of  $E_g$  for a variety of common semiconductors.

It should be noted that the positions of the crystal orbitals on the energy scale in Figures 3 and 4 are located with respect to the vacuum level as reference. The vacuum level is defined

**Figure 4** A schematic representation of the band structure of a semiconductor. The shaded area denotes a fully occupied band and the unshaded area denotes an empty band. Two nonvalence bands are also drawn to stress the point that the valence band of a semiconductor is the highest occupied band.  $E_{cb}$  and  $E_{vb}$  represent the conduction band edge and the valence band edge, respectively, and  $E_g$  is the band gap. When photons with energy greater than the band gap are absorbed by the semiconductor, electrons are excited from the semiconductor valence band into the conduction band

**Table 1** Properties of some common semiconductors<sup>a</sup>

| Semiconductor                                                                | Crystal structure | Band gap (eV) <sup>b</sup> | Type of band gap |
|------------------------------------------------------------------------------|-------------------|----------------------------|------------------|
| Si                                                                           | Diamond           | 1.12                       | Indirect         |
| Ge                                                                           | Diamond           | 0.66                       | Indirect         |

as the energy level of an electron in vacuum, and is taken to be zero eV on the energy scale. Note also that although the physics convention assigns more negative energies to electrons that are more tightly bound relative to vacuum (for example, the energy of a 1s orbital in the H atom is  $-13.6$  eV), the energy scale used by most electrochemists is opposite in sign, with more tightly bound electrons having more positive energies relative to the vacuum level. The assignment on the electrochemical energy scale is based on a ‘work function’ convention, which refers to the energy required to remove an electron from a particular electronic state in the solid.

### 3.1.3 Density of States in the Energy Bands of a Semiconductor

An important numerical quantity that describes the electronic structure of a semiconductor is the density of electronic states within a band. The density of electronic states per unit of energy can be obtained in a qualitative fashion by assuming that the crystal acts like a potential well and by treating the electron as a particle in a box.<sup>11,17,19</sup> Since the motions of electrons in a crystal are restricted by the delocalized orbital structure of the solid, the apparent mass of the electron is different from its mass in a vacuum.

This ‘effective’ mass,  $m_e^*$ , describes the movement of an electron under the influence of the periodic potential in the lattice. The value of  $m_e^*$  can be calculated from the band structure of the semiconducting solid, and can also be measured experimentally using cyclotron methods.<sup>10</sup>

When the value of the effective electron mass is known, the resulting expression for the density of states in the conduction band is

$$N_{cb}(E) = \frac{4\pi(2m_e^*)^{3/2}}{h^3}(E_{cb} - E)^{1/2} \quad (E \leq E_{cb}) \quad (1)$$

where  $h$  is Planck’s constant and  $N_{cb}(E)$  describes the density of electronic states in the conduction band as a function of energy,  $E$ . In this formalism, the influence of the periodic lattice potential on  $N_{cb}(E)$  is contained in the value of the effective mass,  $m_e^*$ . A similar expression can be obtained to describe the density of electronic states in the valence band, and in all other bands, of the semiconducting solid.

The density of states is useful to our discussion because it allows the calculation of an extremely important numerical quantity, the effective density of states in the conduction band of the semiconductor,  $N_c$ . As a first approximation,  $N_c$  can be considered to be the number of electronic states in the conduction band of the semiconductor that are available to accept electrons from a donor.  $N_c$  is more formally defined as the number of electronic states,  $N(E)$ , for all energy  $E$  within  $3kT$  of the conduction band edge [ $|(E_{cb} - E)| < 3kT$ ]. Given the density of states per unit energy (equation 1), and using Fermi–Dirac statistics to describe the distribution of electrons as a function of energy, it can be shown that<sup>10,11,17</sup>

$$N_c = 2 \left( \frac{2\pi m_e^* kT}{h^2} \right)^{3/2} \quad (2)$$

Typically,  $N_c \approx 10^{19}$  states  $\text{cm}^{-3}$ . A similar equation can be derived for the valence band, and the effective density of states in the valence band,  $N_v$ , is also  $\approx 10^{19}$  states  $\text{cm}^{-3}$ .

### 3.1.4 Chemical and Electronic Properties of Semiconductors

In general, semiconductors can have different types of valence band and conduction band structures. These differences can affect the chemical reactivity of the various types of semiconducting solids. For example, in a covalent solid such as Si, the valence and conduction bands can be considered as crystal orbitals that are either bonding or antibonding combinations of hybridized Si atomic orbitals. This situation is closely related to our polyene example, where the valence band consisted of bonding  $\pi$ -orbitals and the conduction band consisted of antibonding  $\pi^*$ -orbitals. However, in an ionic crystal such as TiO<sub>2</sub>, the valence band is composed of crystal orbitals that are derived from the filled O<sup>2-</sup> 2p orbitals, while the conduction band is composed of crystal orbitals that are

derived from the empty 3d orbitals of  $\text{Ti}^{4+}$ .<sup>26–29</sup> In this case, the band gap is not an energy gap between bonding and antibonding bands of the same symmetry. Rather, it is the energy gap between two very different types of bands.

The electronic band structure of solids is also useful in explaining many chemical properties of semiconductors. For example, ionic semiconductors are generally more stable towards corrosion and passivation than covalent semiconductors. This observation can easily be rationalized using the frontier molecular orbital argument (*see Frontier Orbitals*), which states that chemical reactivities are often controlled by the size of the HOMO–LUMO gap.<sup>30,31</sup> For semiconductors, the HOMO–LUMO gap is the band gap, and therefore the chemical reactivity of semiconductors should be related to the value of  $E_g$ . In a covalent semiconductor, the crystal orbitals that comprise the valence band and the conduction band are reasonably close in energy. The band gaps of these materials are relatively small, and these semiconductors are thus expected to be chemically reactive. This prediction is in agreement with experiment. In fact, one of the key problems in using small band gap semiconductors in energy conversion applications is their tendency to undergo corrosion and passivation reactions.<sup>2</sup> In contrast, the crystal orbitals that make up the valence and conduction bands of ionic semiconductors ( $\text{TiO}_2$ ,  $\text{SrTiO}_3$ , etc.) are generally very different in energy, so their band gaps are usually very large. These solids should therefore be less prone to undergo oxidation or corrosion reactions. This prediction is also consistent with experimental results, and accounts for the emphasis on the use of metal oxides in water photoelectrolysis.<sup>32–34</sup>

The orbital character of the valence and conduction bands can also be used to understand trends in the electronic properties of semiconductors. For example, even though the value of  $E_g$  varies a great deal in metal oxide semiconductors (Table 1), the energies of the valence band edges are quite similar throughout this series of solids. This similarity can be understood from our MO/band structure treatment, as the valence bands of these semiconductors are constructed predominantly from the 2p orbitals of  $\text{O}^{2-}$ . The MOs that arise from these atomic orbitals should therefore be similar in bonding character and in energy. Within this framework, changes in the lattice cation will primarily affect the energy of the conduction band edge. This prediction is consistent with experimental data for metal oxide semiconductors.<sup>35–39</sup>

This latter behavior has been generalized to extend beyond the metal oxide semiconductor series. A general guideline has been proposed that the valence band character of most semiconductors is dominated by orbitals that are derived from atomic orbitals of the lattice anion.<sup>40</sup> To the extent that this generalization is valid, it predicts that semiconductors with a given lattice anion will have valence band edge energies similar to other materials with the same lattice anion. This rule also predicts that changes in the lattice cation will be reflected primarily in the energy of the conduction band

edge (and therefore also in the band gap energy). This generalization is called the *Common Anion Rule*.<sup>40</sup> Although the common anion rule has received some experimental and theoretical support,<sup>38,41–48</sup> it is at best a rough generalization of chemical and electronic behavior. This generalization is not expected to be rigorously valid for any wide series of materials, especially for solids with different crystal structures or lattice stoichiometries.

Another analogy to chemical systems can be made when considering the reactivity of excited states of semiconductors. In molecular systems, it is well known that the types of orbitals in the HOMO and LUMO can determine the chemical reactivity of the excited electronic states of a molecule. A similar argument can be applied to predict the reactivity of different semiconductors. For example, it has been suggested that van der Waals semiconductors such as  $\text{MoS}_2$  should be more stable towards corrosion and passivation reactions than II–VI semiconductors such as  $\text{CdS}$ .<sup>49,50</sup> This prediction was based on calculations that revealed that the valence and conduction bands of  $\text{MoS}_2$  are both largely Mo 3d in character. For  $\text{MoS}_2$ , excitation of an electron is expected to result in the transfer of an electron from one metal-derived orbital set (in the valence band) to another metal-derived orbital set (in the conduction band), so no photocorrosion processes should be initiated. In contrast, the valence band of  $\text{CdS}$  is  $\text{S}^{2-}$  in character, and the conduction band is  $\text{Cd}^{2+}$  in character. For  $\text{CdS}$ , excitation of an electron from the valence band to the conduction band is expected to remove an electron from the  $\text{S}^{2-}$ -derived orbitals, and should provide an initial step towards the dissolution of the lattice anion as the neutral  $\text{S}^0$  species. These predictions have been partially verified by experiment, as metal dichalcogenide electrodes are often more stable in contact with aqueous solutions than are II–VI compounds.<sup>2</sup>

### 3.2 Optical Characteristics of Semiconductor Materials

In a semiconductor, some of the most important electronic transitions arise from the optical excitation of an electron across the semiconductor band gap. This excitation leads to the promotion of an electron from an orbital in the valence band to an orbital in the conduction band. This fundamental and extremely important process is crucial to the use of semiconductors as photovoltaic devices, photonic detectors, and optical switches. It is possible to understand the optical properties of semiconductors using the band structure formalism described above.

The light absorption process in semiconductors has an energy threshold. The value of this threshold is the band gap energy,  $E_g$ . Only photons with energies greater than or equal to the band gap energy can induce an electronic transition in the semiconductor. Large band gap materials such as  $\text{TiO}_2$  will therefore only absorb light at short wavelengths, whereas small band gap materials such as Si and GaAs will respond to larger portions of the electromagnetic spectrum.

The band gaps of common semiconductors can vary from near-zero ( $E_g = 0.1$  eV for  $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ ) to greater than 3 eV ( $E_g = 3.2$  eV for  $\text{SrTiO}_3$ ).

From Beer's law, the absorbance and transmittance of a material can be expressed as

$$A = \ln \frac{I_0}{I} = \varepsilon cl \text{ and } T = \frac{I}{I_0} = \exp(-\varepsilon cl) \quad (3)$$

where  $I$  is the transmitted light intensity,  $I_0$  is the incident light intensity,  $\varepsilon$  is the molar extinction coefficient,  $l$  is the optical path length, and  $c$  is the concentration of absorbing material. For solids, the concentration of the absorber is a constant, so Beer's law can be rewritten as

$$A = \ln \frac{I_0}{I} = \alpha l \text{ and } T = \frac{I}{I_0} = \exp(-\alpha l) \quad (4)$$

where  $\alpha \equiv \varepsilon c$  is the absorption coefficient of the material. This latter expression is usually used for expressing light absorption in solids. In this expression,  $\alpha$  is a function of the wavelength at which the light absorption is measured.

For molecules, the extinction coefficient,  $\varepsilon$ , of an electronic transition can vary over a wide range of values, depending on whether the transition is optically and/or spin allowed. For semiconductors, the same restrictions apply. At the wavelength of interest, the electronic transition from one band to another must be optically and spin allowed to have a high extinction coefficient, that is to have a large absorption coefficient,  $\alpha$ . Semiconductors that display a fully allowed transition between the valence band and the conduction band are referred to as direct band gap semiconductors. In these materials, such as GaAs and CdTe, the absorption coefficients are large, and the light is strongly absorbed close to the surface of the solid. Typical values of  $\alpha$  for these materials are  $10^4$ – $10^5$   $\text{cm}^{-1}$ . Figure 5 depicts a plot of the absorption coefficient versus wavelength for a typical direct band gap semiconductor, GaAs.

For other semiconductors, such as Si, the lowest energy electronic transition between the valence band and the conduction band is formally optically forbidden. These materials are said to have an indirect band gap. Indirect band gap materials generally display small absorption coefficients for photons near the band gap energy. This behavior is analogous to a d–d electronic absorption band in an octahedral transition metal complex, which is formally optically forbidden owing to the inversion symmetry of the d orbitals. In such complexes, d–d transitions are generally observed experimentally, albeit with weak extinction coefficients, because other mechanisms allow the light absorption process to conserve momentum when the entire molecular wavefunction is considered. Similarly, for indirect band gap semiconductors, light absorption is allowed only when the momentum of the photon is coupled to vibrations of the crystal lattice and to the lowest energy electronic transition. Because of this requirement, the photon absorption process

**Figure 5** A plot of absorption coefficient versus photon wavelength for Si and GaAs.<sup>24</sup> A direct band gap semiconductor, such as GaAs ( $E_g = 1.42$  eV), has a sharp onset of absorption at photon energy  $= E_g$  and a large absorption coefficient for  $h\nu > E_g$ . The indirect band gap semiconductor Si ( $E_g = 1.12$  eV) has a broad, weak onset of absorption, which begins at photon energies  $\leq E_g$  owing to vibrational coupling with the crystal lattice. For Si, note the low value of the absorption coefficient at photon energies substantially higher than the band gap energy

is less likely to occur, and indirect band gap semiconductors therefore have small absorption coefficients. For example, although the band gap energy for Si is 1.12 eV, the absorption coefficient at photon energies of 1.3 eV is still only  $10^2$   $\text{cm}^{-1}$  (Figure 5). This contrasts with the value of  $10^4$   $\text{cm}^{-1}$  that is typically displayed by direct band gap materials at photon energies 0.1–0.2 eV higher than  $E_g$ .<sup>11</sup> Examples of other indirect band gap semiconductors include GaP and  $\text{TiO}_2$ .

For direct band gap materials, the absorption coefficient generally increases rapidly when  $h\nu$  is approximately equal to  $E_g$ , and it then remains at large values when  $h\nu$  is much greater than  $E_g$ . For indirect band gap materials, the absorption coefficient is generally a much more slowly rising function of energy, with  $\alpha \propto (h\nu - E_g)^2$  (for  $h\nu \geq E_g$ ) being a typical dependence of the absorption coefficient on the energy of the incident photon.<sup>11</sup> In both cases, all of the incident light can be absorbed if the sample is sufficiently thick, because, as indicated by equation (4), increases in  $l$  will produce increases in absorbance. Note, however, that as the photon energy increases, the indirect band gap material will eventually enter a regime where it absorbs light almost as effectively as a material with a direct band gap.

A related, useful quantity for characterizing the absorption of light by semiconductors is the optical penetration depth (Figure 5). This quantity is defined as the inverse of the absorption coefficient; that is, penetration depth  $\equiv \alpha^{-1}$ . From equation (4), it can be seen that the penetration depth is the distance into the semiconductor at which the transmitted light intensity reaches  $1/e$  of the incident light intensity at the surface of the solid. In general, when compared to direct

band gap semiconductors, indirect band gap semiconductors have larger penetration depths, and therefore require thicker samples to fully absorb the incident light.

One important optoelectronic application of semiconductors is as photovoltaic energy conversion devices. For efficient solar energy conversion, a semiconductor needs to be thick enough to absorb essentially all the incident photons with energies greater than  $E_g$ . For example, Si, an indirect gap semiconductor, has a value of  $\alpha$  equal to  $10^2 \text{ cm}^{-1}$  for photon energies near  $E_g$  (Figure 5). This value implies that greater than  $100 \mu\text{m}$  of Si must be used to absorb the incident light effectively in this energy range. This value places severe restrictions on the type of cells, and on the quality of crystals, that must be used in any efficient Si-based solar energy conversion device. This situation contrasts with that for the direct band gap semiconductor GaAs, in which  $\alpha$  is approximately  $10^4 \text{ cm}^{-1}$  near  $E_g$  (Figure 5). The large absorption coefficient of this direct band gap semiconductor implies that only  $1\text{--}2 \mu\text{m}$  of GaAs are needed to harvest the incident photons effectively near the GaAs band gap energy. Similar considerations apply, of course, to the use of semiconductors in other optical applications, such as in photonic detectors and optical switching applications.

## 4 CARRIER STATISTICS FOR SEMICONDUCTORS

With the above description of the band structure and optical properties of semiconductors, it is now possible to describe the remaining key characteristic of semiconductors: electrical conductivity. The electrical conductivity of semiconductors forms the basis for most of the modern electronics industry. Without precise control over the electrical conductivity of semiconductors, many modern electronic devices would not perform satisfactorily. The goal of this section is to understand the chemical basis for the electrical properties of semiconducting solids.

### 4.1 Carrier Concentrations in an Intrinsic Semiconductor

First, the properties of the undoped, intrinsic semiconductor (i.e. the pure semiconductor) must be considered. Although semiconductors have been described as having a filled HOMO (the valence band) and an empty LUMO (the conduction band), this condition is only rigorously true at absolute zero. At any finite, nonzero temperature, thermal excitation within the solid will result in promotion of carriers from one band to the other. This promotion of carriers produces a nonzero conductivity of the semiconductor. This situation is described quantitatively in this section.

Before proceeding with this discussion, it is important to realize that there are two different types of charge carriers

in a semiconductor: electrons and holes. The promotion of an electron from the valence band into the conduction band, either by thermal or optical excitation, produces a free electron in the conduction band and an electronic vacancy in the valence band. This electronic vacancy is commonly referred to as a hole. Although the motion of holes is actually a representation of the motion of the remaining collection of valence band electrons, a hole can formally be treated as a discrete particle with a positive electronic charge. In general, most of the properties of electrons in the valence band can also be calculated formally as properties of holes. For example, the effective mass of a hole can be calculated similarly to that of an electron. However, owing to differences between the electronic structures of the valence and conduction bands, it is important to realize that the effective mass of a hole in the valence band may be quite different from the effective mass of an electron in the conduction band. The hole formalism is, however, quite useful in concisely describing the charge carrier motion in the valence band of a semiconductor.

Like an electron, a hole can act as a charge carrier. For example, a hole moving towards a contact is physically identical to an electron in the valence band moving away from that contact. Because both electrons and holes contribute to the current in a semiconductor sample, we will use the more general term charge carriers to refer to either electrons or holes in a semiconductor.

To describe the conductivity of an intrinsic semiconductor sample quantitatively, we need to calculate the concentrations of both types of charge carriers in the solid. The key quantity that controls the equilibrium concentration of electrons and holes in an intrinsic semiconductor is the band gap. Because the thermal excitation energy required to produce an electron and a hole is equal to  $E_g$ , the intrinsic carrier concentrations can be related to  $E_g$  using the Boltzmann relationship:<sup>51</sup>

$$n_i p_i = \text{constant} \times \exp\left(-\frac{E_g}{kT}\right) \quad (5)$$

In this equation,  $k$  is the Boltzmann constant,  $T$  is the absolute temperature, and  $n_i$  and  $p_i$  are the electron and hole concentrations at equilibrium in the intrinsic semiconductor, respectively. Both  $n_i$  and  $p_i$  are expressed as particles  $\text{cm}^{-3}$ , which is often abbreviated as ' $\text{cm}^{-3}$ '. The constant in equation (5) is actually a function of the band structure of the solid and is numerically equal to the product of  $N_c$  and  $N_v$ .<sup>51</sup> It is clear that this type of Boltzmann relationship should correctly describe the concentrations of electrons in the conduction band and of holes in the valence band that exist as a result of thermal excitation across the band gap at any given temperature.

Realizing that the thermal excitation to promote an electron into the conduction band must also result in the formation of a hole in the valence band, we can set  $p_i = n_i$ . This equivalence

leads to the following relationship between  $n_i$  and  $E_g$ :

$$n_i^2 = N_c N_v \exp\left(-\frac{E_g}{kT}\right) \quad (6)$$

This equation is essentially an equilibrium constant relationship between the electron and hole concentrations in the semiconductor. It is much like the ionization constant expression for the dissociation of water, which can be related to the concentrations of  $H^+(aq)$  and  $OH^-(aq)$  through the relationship  $[H^+][OH^-] = K_w = 1 \times 10^{-14} \text{ M}^2$ . The only difference between these two expressions is that the temperature dependence of the water dissociation equilibrium constant is contained implicitly in the value of  $K_w$ , but is explicit in the relationship expressed by equations (5) and (6). The most important point to remember is that increases in the sample temperature will produce exponential increases in the electron and hole concentrations for an intrinsic semiconductor. Thus, the conductivity of intrinsic semiconductors increases exponentially with temperature. In contrast, the conductivity of metals decreases with increasing temperature.<sup>10</sup>

We can now estimate the intrinsic carrier concentrations for many semiconductors. We merely use equation (6) with the appropriate values of  $N_c$  and  $N_v$  for each material. As described above,  $N_c$  and  $N_v$  have similar values and are typically  $\approx 10^{19} \text{ cm}^{-3}$ . If these values are not known, they can be calculated from the band structure according to equation (2). For Si ( $E_g = 1.12 \text{ eV}$ ),  $n_i$  is only  $1.45 \times 10^{10} \text{ cm}^{-3}$ . In general, samples with higher band gap energies will typically have lower values of  $n_i^2$ . For example, considering GaAs ( $E_g = 1.42 \text{ eV}$ ) and using the actual values of  $N_c$  and  $N_v$  for GaAs at  $T = 300 \text{ K}$  in equation (6), we calculate that the equilibrium concentrations of electrons and of holes at room temperature are  $1.79 \times 10^6 \text{ cm}^{-3}$ .

For most semiconductors,  $kT$  (0.0259 eV at 300 K) is much smaller than  $E_g$ . Thus, few electrons and holes are produced at room temperature in such semiconductors. Intrinsic samples are far too resistive for many applications; additionally, in actual semiconductor samples, the concentration of unwanted impurities often exceeds the intrinsic carrier concentrations. Under these conditions, it is difficult to maintain quality control over the electrical properties of semiconductors. For these reasons, the conductivity of semiconductors is generally deliberately controlled through a process known as doping.

## 4.2 Carrier Concentrations in a Doped Semiconductor

Because the intrinsic carrier concentrations in semiconductors are so low, even impurity concentrations at the level of one part per billion can have a profound effect on the electrical properties of a semiconductor sample. To increase the sample conductivity and to control other electronic properties of the semiconductor, low concentrations of specific impurity atoms are often introduced into the crystal lattice. This process, which is called doping, serves to decrease the resistance

of the crystal. Doping also allows control over the Fermi level (i.e. the electrochemical potential) of the semiconductor phase. The strategy for introducing dopant atoms, as well as some quantitative properties of doping statistics, is described in this section.

### 4.2.1 Chemistry of Dopants: Donors versus Acceptors

Dopant atoms can be either donors or acceptors. Donors are readily ionized to produce electrons in the conduction band and positive charges on the dopant atoms; acceptors scavenge electrons to produce holes in the valence band and negative charges on the dopant sites. A material that has been doped with donors is called an n-type semiconductor, while one that has been doped with acceptors is called a p-type semiconductor. These designations can be easily remembered by the sign of the predominant charge carrier. Donors create free electrons, which have a negative charge, so the sample is denoted n-type. Similarly, acceptors create holes, which have a positive charge, so the sample is denoted p-type. The predominant charge carrier is called the majority carrier, so electrons are the majority carriers in an n-type sample and holes are the majority carriers in a p-type semiconductor.

Figure 6 displays the energy levels of common donors and acceptors with reference to the band edges of two semiconductors. If the energy levels of these donors and acceptors are close to the conduction or valence bands, respectively, they are called shallow donors or acceptors. Dopants with energy levels that are further away from either band are called deep dopants. While ionization of shallow dopants is usually complete at room temperature, ionization of deep dopants generally does not occur at room temperature. Shallow dopant materials are considered primarily in the remainder of this section.

The properties of most common dopants can be surmised from simple atomic ionization energies and from trends in the periodic properties of the elements. For example, in Si, which is a group 14 element, group 15 elements such as P or As (which have lower ionization energies than Si) will act as donors. Since only four of the five valence electrons in P are required for tetrahedral bonding in the crystal, the fifth valence electron will be donated to the conduction band at room temperature. This situation will produce an n-type semiconductor, in which the majority carriers are electrons. To a good approximation, the group 15 atom in the Si lattice could be considered as being a positively charged P core with a loosely bound electron, as depicted in Figure 7(a).

Conversely, group 13 elements such as B or Al are acceptors in Si, since they require an additional electron from the valence band to satisfy the tetrahedral bonding requirement. The group 13 atom in the Si lattice can be considered as a negatively charged B core with a loosely bound hole (Figure 7(b)). Since the trapping of an electron by the group 13 dopant atom results in the ionization of an electron from a lattice Si site, the doping process with the group 13 element produces an excess number

**Figure 6** Above: schematic drawing of the energy levels of ‘shallow’ (a) donor and (b) acceptor dopants.  $E_{cb}$  and  $E_{vb}$  represent the conduction band edge and the valence band edge, respectively.  $E_F$  is the Fermi level. For a semiconductor doped with donors, the Fermi level is closer to the conduction band edge, while  $E_F$  is closer to the valence band edge for a semiconductor doped with acceptors. Below: representation of typical dopant levels for (c) GaAs and (d) Si in relation to the band edges.<sup>11</sup> The numbers near these levels denote the difference in energy (eV) away from the nearest band edge. Dopant levels that are close to the middle of the band gap are referred to as ‘deep’ dopant levels. In (d), an example of a compensator, Au, is shown, with an acceptor energy level above the donor, so that any Au dopant renders the Si crystal ‘more intrinsic’. The two dopant levels of Zn are also represented

of holes in the valence band. Doping Si with B thus leads to a p-type Si sample. In such a p-type sample, the holes are the majority carriers, while the electrons are the minority carriers.

In some special cases, such as when Si is used as a dopant in GaAs, dopants are amphoteric. Amphoteric dopants can either be donors (Si in Ga sites of GaAs) or acceptors (Si in As sites of GaAs), depending on the crystal growth conditions (Figure 6(c)). Au in Si can best be described as a compensator, because its incorporation always reduces the number of free carriers in the sample. This occurs because Au has both a donor level and an acceptor level, with the acceptor level higher in energy (closer to vacuum) than the donor level (Figure 6(d)). Ionization of the gold dopant levels will therefore tend to make Si samples more intrinsic, regardless of whether the Si is initially n-type or p-type.

Other impurity atoms, such as transition metals, can have deep levels or multiple levels. An example of this situation is Zn in Si. Zn differs from Si by two valence electrons, so

the Zn dopants can accept either one or two electrons from the Si valence band. However, owing to Coulombic repulsion and reorganization of the lattice atoms around the dopant, the energy of the singly charged state is different from that of the doubly charged state. This difference produces two distinct dopant energy levels for Zn in Si (Figure 6(d)).

Interstitial atoms and crystal defects can also behave as dopants. This type of doping is important for n-type CdS. Typical growth conditions for CdS yield S vacancies in the lattice, and the excess Cd then acts as an n-type dopant. For this reason, no p-type CdS has yet been prepared. CdSe and CdTe, however, have been grown in p-type forms, because they can be obtained in more defect-free crystalline phases and thus doping is more effective in controlling the carrier concentration of these purer solids.

The introduction of crystal defects such as oxygen vacancies is also an important mechanism for doping metal oxides. In fact, many of the n-type doping processes for

**Figure 7** A schematic representation of dopant atoms in a Si lattice: (a) P-doped Si lattice, and (b) B-doped Si lattice. The dopant atoms are shown as replacing a Si atom in the crystal lattice. The circles represent schematic Bohr radii of the carrier (i.e. an electron (–) or a hole (+)) around the dopant atom. Note that these orbits are not drawn to scale; in reality, the first Bohr radius of these carriers is about 12 Å,<sup>57</sup> and a single carrier is spread over about  $10^3$  Si atoms

materials such as ZnO and TiO<sub>2</sub>, which involve ‘reduction’ with H<sub>2</sub>, actually create oxygen vacancies in the lattice.<sup>2</sup> The actual role of the H<sub>2</sub> is to combine with the lattice anions to form H<sub>2</sub>O, which is expelled from the crystal. The reaction with H<sub>2</sub> creates the desired oxygen vacancies in the metal oxide lattice. These anion vacancies leave the surrounding lattice cations uncompensated. The electrons from these uncompensated metal ions then act as dopants, and make the entire crystal n-type in electrical properties. Formation of interstitials is also a possible mechanism for doping oxide semiconductors such as TiO<sub>2</sub>. However, oxygen vacancies are generally viewed as the dominant doping process at low temperatures and higher oxygen partial pressures, while Ti interstitials may dominate the TiO<sub>2</sub> doping process at high temperatures and lower oxygen partial pressures.<sup>2</sup>

All of these factors can significantly affect the electronic properties of a semiconducting material, even if the dopant

atoms exist in the crystal in concentrations of parts per billion. The manufacturing and processing of most semiconductor materials and devices are therefore conducted under conditions of excruciating cleanliness in order to minimize the incorporation of unwanted impurities. For most samples of technological importance, doping is performed using the straightforward concepts that have been described above. For certain applications, impurities with deep levels are incorporated into the semiconductor to control properties that cannot be easily manipulated by shallow dopants.<sup>11,23,52</sup>

#### 4.2.2 Carrier Concentrations in a Doped Semiconductor

Because shallow dopant atoms are readily ionized at room temperature, the electron concentration,  $n$ , in an n-type semiconductor is closely approximated by the concentration of donor atoms,  $N_d$ , in the lattice. Rigorously, the electron concentration is given by the sum of the electrons thermally generated from the Si atoms and those generated by the thermal ionization of dopants. However, because  $n_i$  is so small for most common semiconductors,  $n = n_i + N_d \approx N_d$  for any reasonable dopant concentration ( $10^{14}$ – $10^{18}$  dopant atoms cm<sup>–3</sup>). Similarly, for a p-type semiconductor, the hole concentration is approximately equal to the acceptor concentration,  $N_a$ . This approximation holds because shallow acceptors are essentially all ionized at room temperature, and the intrinsic hole concentration,  $p_i$ , is generally negligible compared to the number of holes that are generated by the dopants. Clearly, control over the dopant density of a semiconductor allows the manipulation of the carrier concentrations.

It is also important to calculate the equilibrium concentration of holes in a doped n-type semiconductor and of electrons in a doped p-type semiconductor. These minority carrier concentrations are readily obtained using the concepts described above, because equations (5) and (6) are actually more general than has been indicated. As mentioned above, the relationship between  $n_i$  and  $p_i$  in equation (5) is actually an equilibrium constant relationship between the electron and hole concentrations in the solid. In the discussion above, this expression was derived under the special constraint that  $n_i = p_i$ , that is under thermal excitation conditions. However, the equilibrium constant relationship on the right-hand side of equations (5) and (6) must hold regardless of the source of electrons and holes, so it applies to both doped and intrinsic semiconductor samples. We thus obtain

$$np = n_i^2 = N_c N_v \exp\left(-\frac{E_g}{kT}\right) \quad (7)$$

as the general relationship between the electron and hole concentrations in any given semiconductor. In equation (7),  $n$  and  $p$  denote the equilibrium majority and minority carrier concentrations, respectively, in an n-type semiconductor, or vice versa in a p-type semiconductor.

This relationship is often called the *law of mass action* when applied to semiconductor doping statistics.<sup>11</sup> The situation is again conceptually identical to that for the equilibrium constant relationship for aqueous acid/base dissociation. The relationship  $K_w = [\text{H}^+(\text{aq})][\text{OH}^-(\text{aq})]$  holds not only for the neutral liquid (i.e. the ‘intrinsic’, pH = 7 sample), but also for the proton and hydroxide concentrations in the presence of externally added sources of  $\text{H}^+(\text{aq})$  or  $\text{OH}^-(\text{aq})$  (i.e. the extrinsic or ‘doped’ liquid). In the doped semiconductor, we are merely adding electrons or holes to control the carrier concentrations in the same way that the pH of water can be manipulated through the addition of acid or base.

#### 4.2.3 Conductivity

The most important feature of the doping process is that it affects the electrical conductivity of the semiconductor sample. However, the doping process directly produces changes in the concentration of free charge carriers in the semiconductor, and indirectly produces changes in the electrical conductivity of the specimen. To understand the relationship between the charge carrier concentration and the electrical conductivity of a semiconductor, it is necessary to describe the macroscopic motion of charge carriers through the semiconducting solid. To describe this process, we first need to consider the motion of charge carriers when no electric field is present in the solid. We will then modify this discussion to incorporate the effects of electric fields in the system.

As described above, the electrons in a semiconductor can be described classically with an effective mass,  $m_e^*$ , which is usually less than the free electron mass. When no gradients in temperature, potential, concentration, and so on are present, the conduction electrons will move in random directions in the crystal. The average time that an electron travels between scattering events is the mean free time,  $\tau_m$ . Carrier scattering can arise from the collisions with the crystal lattice, impurities, or other electrons. However, during this random walk, the thermal motion is completely random, and these scattering processes will therefore produce no net motion of charge carriers on a macroscopic scale.

Now we consider the charge carrier motion when an electric field is applied to the semiconducting solid. The electric field,  $\mathcal{E}$ , will result in a force,  $F = -q\mathcal{E} = m_e^*a$ , on the electron, where  $a$  is the acceleration of the electron due to the electric field. Under these conditions, the electron will still move with its average thermal velocity. However, in the presence of the electric field, the electron will also acquire a drift velocity,  $v_d$ . The drift velocity will be directed in the opposite direction from the electric field, and this directed motion will propel the electrons through the crystal even though they still undergo scattering events (Figure 8).<sup>51</sup> The drift velocity and the electric field can be related through the mean free time between scattering events,  $\tau_m$ :

$$v_d = a\tau_m = -q\left(\frac{\tau_m}{m_e^*}\right)\mathcal{E} \quad (8)$$

**Figure 8** A schematic representation of the motion of charge carriers in a semiconductor lattice.<sup>51</sup> (a) A charge carrier in the absence of any external field. The thermal motion is random, and will not lead to any motion of the charge carrier on a macroscopic level. (b) A charge carrier in the presence of an electric field. The charge carrier motion due to the electric field is imposed upon its thermal motion. (c) The carrier drift shown at the macroscopic level. The random thermal motion of the charge carrier again leads to no motion on the macroscopic level. The charge carriers are propelled by the electric field at a constant velocity,  $v_d$ , either parallel or antiparallel to the applied field

A similar equation can be used to describe the motion of holes, except that holes will move toward the electric field rather than away from it.

The proportionality constant between the applied electric field and the resulting drift velocity is called the charge carrier mobility,  $\mu$ . For electrons,  $\mu_n = q(\tau_m/m_e^*)$ ; for holes,  $\mu_p = q(\tau_m/m_h^*)$ . It should be noted that, owing to differences in the effective masses of electrons and holes, their mobilities within a semiconductor may be markedly different. The electrical conductivity,  $\sigma$ , of a semiconductor is related to the free carrier concentrations by:

$$\sigma = qn\mu_n + qp\mu_p \quad (9)$$

This equation states that the electrical conductivity due to a free carrier is the product of the charge on the carrier,  $q$ , its concentration in the solid, and its mobility,  $\mu$ . Since semiconductors have two different types of mobile charge carriers, electrons, and holes, the total sample conductivity,  $\sigma$ , is simply the sum of the individual conductivities due to each carrier type. It should be noted that the conductivity depends only on the absolute number of carriers, and therefore is not affected by the signs of the carriers themselves. Carrier mobilities for electrons and holes in a variety of semiconductors can be measured experimentally. These values have been tabulated in various reference books<sup>10,11,22,23</sup> and are available for many semiconductors of interest. Doping of a semiconductor therefore allows precise control over the conductivity of the semiconductor sample.

### 4.3 Fermi Levels and the Energetics of Semiconductor Samples

The last quantity that is needed to describe the important properties of an isolated semiconductor phase is the electrochemical potential, or *Fermi Level* ( $E_F$ ), of the material. The Fermi level determines the tendency of the semiconductor to transfer charges to other phases. As formally defined in statistical mechanics, the Fermi level of any phase is the energy level where the probability of finding an electron is 1/2. In an intrinsic semiconductor crystal at absolute zero, the Fermi level would be located near the middle of the band gap (Figure 9(a)). At absolute zero, the energy states in the valence band would be totally occupied, while the states in the conduction band would be completely empty. The probability of finding an electron would therefore go from 1.0 in the valence band to 0.0 in the conduction band, and would reach a value of 1/2 at mid-gap (even though there are no actual electronic states at this energy).

For a doped semiconductor, the Fermi level position will be shifted from mid-gap, because the doping process will vary the tendency of the solid to either gain or lose electrons. For example, if donors are added to an intrinsic semiconductor, the material will be more likely to lose electrons. The Fermi level of an n-type semiconductor will thus move closer to the vacuum level (i.e. will become more negative on the electrochemical potential scale) (Figure 9(b)). Similarly, if acceptors are added to an intrinsic material, the Fermi level will become more positive, because this phase will now have an increased tendency to accept electrons from another phase (Figure 9(c)).

The Fermi level of a semiconductor phase can be written as

$$E_F = E_{Fi} - kT \ln \left( \frac{n}{n_i} \right) \quad (10)$$

**Figure 9** A schematic representation of the Fermi level position in a semiconductor. (a) The Fermi level in an intrinsic semiconductor at absolute zero is approximately at mid-band gap. (b) In an n-type semiconductor, the electron concentration in the conduction band is greater than in an intrinsic sample. The Fermi level is thus closer to the conduction band for an n-type sample. (c) In a p-type semiconductor, the Fermi level position is moved closer to the valence band. Thus, a p-type semiconductor is more likely to accept electrons from another phase than is the corresponding n-type semiconductor

or

$$E_F = E_{Fi} + kT \ln \left( \frac{p}{p_i} \right) \quad (11)$$

In these equations, the term  $E_{Fi}$  represents the Fermi level position in the intrinsic semiconductor (i.e. when  $n = n_i$  in equation (10) or  $p = p_i$  in equation 11). This value serves as a reference energy, much as  $\text{pH} = 7$  serves as a reference value for changes in the pH of a neutral aqueous solution. Physically, equation (10) states that doping a semiconductor with donors will produce a more negative Fermi level because  $n > n_i$ . Similarly, the doping of a semiconductor with acceptors yields a more positive Fermi level, as given by equation (11) with  $p > p_i$ . Of course, since  $np = n_i^2$ , equations (10) and (11) can be used interchangeably to solve for  $E_F$  of a doped semiconductor if either  $n$  or  $p$  is known. Both expressions will yield identical numerical values for  $E_F$ . More rigorous equations can be obtained by using Fermi–Dirac statistics on the electron occupancy of the filled and empty states of a semiconductor.<sup>11,52</sup> However, the final results of such a treatment are identical to equations (10) and (11) for most doping conditions.

It is often convenient to refer the Fermi level to reference levels that are close to the band edge energies. If we were to fill up the conduction band with electrons to a value equal to the effective density of states in the conduction band,  $N_c$ , then the Fermi level would shift until it was exactly equal to the energy of the bottom of the conduction band,  $E_{cb}$ . Our new reference level would then be the energy of the Fermi level at the bottom of the conduction band, that is,  $E_F = E_{cb}$ . That is,

$$E_F = E_{cb} - kT \ln \left( \frac{n}{N_c} \right) \quad (12)$$

In essence, this is analogous to shifting the reference level of an aqueous solution to  $\text{pH} = 0$ . Changes in pH could then be calculated relative to the amount of acid in a 1.0 M  $\text{H}^+$  solution, as opposed to calculating pH changes relative to a  $10^{-7}$  M  $\text{H}^+$  solution for neutral water. The result for the Fermi level position versus electron concentration is, of course, identical no matter which formula is used. It is only a matter of convenience as to which reference level is used in the calculation of  $E_F$ . Similarly, we could choose to refer the Fermi level position to the energy of the top of the valence band,  $E_{vb}$ . In this case, the expression for  $E_F$  is:

$$E_F = E_{vb} + kT \ln \left( \frac{p}{N_v} \right) \quad (13)$$

The forms used in equations (12) and (13) are often found in the solid-state physics and chemistry literature.

#### 4.4 Chemical and Electrical Effects of Doping Semiconductors

We have seen that doping is useful for several purposes, in that it allows both the electrical conductivity and the Fermi level position of a semiconductor sample to be controlled readily. Various types of electronic devices can be obtained when the carrier concentrations are manipulated through doping. The conductivity of Si can vary from  $10^{-4} \text{ ohm}^{-1} \text{ cm}^{-1}$  for nearly intrinsic Si to greater than  $10^2 \text{ ohm}^{-1} \text{ cm}^{-1}$  for highly doped n-type or p-type samples. These levels of conductivity correspond to a range of doping levels in Si, for example, from  $10^{12}$  to  $10^{21} \text{ cm}^{-3}$ .<sup>11</sup> The ability to control the electrical properties of these materials allows fabrication of rectifiers, transistors, physical, and chemical sensors, and other electronic devices from semiconducting materials. Further information on the specific doping geometry of electronic devices can be found in numerous textbooks.<sup>11,53-55</sup> It is clear, however, that deliberate manipulation of the electrical conductivity of semiconducting solids is a key feature of doping.

Doping also affects the Fermi levels of semiconducting solids, and therefore affects the chemical reactivity of these phases. The Fermi level is the electrochemical potential of the material, and materials with differing electrochemical potentials must react differently. For example, selective etchants can etch p-type Si, while leaving n-type Si untouched. Another example is the behavior of Si electrodes in contact with aqueous HF solution. Although p-type Si anodes corrode in contact with aqueous HF in the dark, n-type Si anodes are chemically inert in this system unless they are illuminated with photons above the Si band gap energy.<sup>56</sup> These chemical differences are a direct consequence of the different Fermi level positions that are obtained through doping. The Fermi level position is also of importance in semiconductor contacts, and in the formation of numerous other electronic devices. Thus, doping of semiconductors is critical for numerous fundamental and technological reasons.

## 5 SUMMARY

To this point, we have seen how the structural, electronic, optical, and electrical properties of semiconductors can be treated within a common framework. The bonding in the lattice determines the structure of the solid, and the structure of the lattice in turn affects the band structure. This band structure then can be used to describe the chemical, optical, and electrical properties of the semiconducting solid. Thus, chemical control over the electronic properties of semiconductors is an important component of modern research in solid-state chemistry and solid-state physics. The concepts described above enable this process to be understood from a relatively qualitative, chemically based viewpoint. Further

details on specific topics can be obtained in specialized textbooks in solid-state chemistry and physics, but this introduction to the relevant concepts should suffice to provide the inorganic chemist with access to the terminology and concepts of the field.

## 1 INTRODUCTION

Why study short-lived molecules?<sup>1</sup> Those who carry out such studies are perhaps driven by two main ambitions. First, to investigate the structures of compounds with unusual coordination numbers or oxidation states. We can thus make small molecules, for example,  $\text{AlCl}$  or  $\text{OPCl}$  (to take just two of very many examples), that are not stable under ambient conditions. In transition metal chemistry, it is becoming apparent that we cannot predict the structures of ‘open shell’ species, for example, we cannot predict what structure the unsaturated 16-electron carbonyl  $\text{Cr}(\text{CO})_5$  will adopt, simply by knowing that saturated 18-electron  $\text{Cr}(\text{CO})_6$  is octahedral. The second point is to study reaction mechanism. We must know about structures of intermediates fully to understand reaction pathways; *kinetics* alone is not enough.

In considering what we mean by ‘short-lived molecules’, we must be careful to distinguish between thermodynamic stability and kinetic inertness. A compound that is thermodynamically unstable need not be short-lived, provided a high activation barrier exists towards reaction. Such a molecule is said to be kinetically inert. A species that survives for only short periods is said to be *labile*. Thus most of those short-lived species that we will consider in this chapter have a degree of thermodynamic instability coupled with kinetic lability. An added complication arises when we consider photochemical systems. Here the ability of a molecule to absorb light at a particular wavelength and the quantum yield for reaction will determine, to some extent, its lifetime. The broad definition adopted in this article is that a short-lived molecule is one whose concentration decays, under ambient conditions, on a timescale ranging from nanoseconds or even picoseconds to a few seconds.

A comprehensive selection of the relevant chemistry is covered, supported by experiments that highlight two of the main areas of study of short-lived intermediates, namely photochemical reactions and high-temperature systems.

## 2 GENERATION OF SHORT-LIVED MOLECULES

Various means exist for the generation of short-lived intermediates. The first are ‘high energy’ systems such as high-temperature vapors or plasmas, the chemistry of which is often quite complex. The thermodynamics of the system under investigation must be considered carefully before predictions can be made as to what species will be present in the vapor. Thus, for example, evaporation of silica,  $\text{SiO}_2$ , yields  $\text{SiO}$  rather than  $\text{SiO}_2$  molecules. This observation reflects the greater thermodynamic stability of the monoxide over the dioxide at the temperature (ca. 2000 K) at which vaporization takes place. Many other similar examples are known; sometimes the nature of the vapor-phase species depends upon the material of the vessel from which the species are evaporated. Thus evaporation of sodium phosphate ( $\text{Na}_3\text{PO}_4$  or  $\text{Na}_5\text{P}_3\text{O}_{10}$ ) from a boat made of a reducing metal such as Mo or Ta yields sodium phosphite ( $\text{NaPO}_2$ ) molecules in the vapor. Reduction of phosphorus also occurs if  $\text{OPCl}_3$  vapor is passed over silver heated to 1100 K. Here the gaseous product is  $\text{OPCl}$ .

Two other systems that produce ‘high-temperature’ molecules should be mentioned: shock waves and flames. Shock waves are typically formed by the rapid release of a high pressure of gas in a shock-tube apparatus. A shock wave is formed that can travel at several times the speed of sound; temperatures as high as 20 000 K have been produced in shock tubes. Thus the method is ideal for monitoring pyrolysis and oxidation reactions. Flames are gaseous systems where a flow of gas combines with a self-supporting reaction to produce a steady-state situation. Again, oxidation reactions are amenable to this approach. In particular, short-lived intermediates in hydrocarbon oxidation, such as  $\text{C}_2$ ,  $\text{OH}$ , and  $\text{CHO}^+$ , have been identified in flames.

Plasmas are another example of a ‘high energy’ gas-phase system. The flow discharge, excited by microwave, radio frequency, or electric discharge, has been much used by chemists to generate reactive species. The system operates at low pressure and at moderate temperatures (ca. 600 K). The plasma contains electrons, ions (positive and negative), and neutral species (atoms, free *radicals* and molecules). Secondary reaction products may sometimes be formed in a plasma, for example, via the intermediacy of fluorine atoms formed when  $\text{CF}_4$  or  $\text{NF}_3$  gas is flowed through a discharge. Such a method has been used, for example, to generate methyl radicals:

A rather different route to short-lived intermediates is to irradiate a suitable precursor with radiation of an appropriate energy. Most common is UV–visible photolysis. Section 5 discusses some of the rich photochemistry displayed by transition metal carbonyls, these being very amenable to UV–visible photolysis. Thus unsaturated carbonyl fragments may be produced:<sup>2,3</sup>

For some reactions, however, higher energy radiation is required. Vacuum UV photolysis may be useful to initiate reactions of molecules that only absorb at short wavelengths. To form matrix-isolated radical cations of various aromatic compounds, for example, (1) and (2). Andrews and coworkers have devised a system for windowless photolysis of a low-temperature matrix (since most window materials will absorb vacuum UV light). A glow discharge of Ar or H<sub>2</sub> is used (the latter has strong emission centered at 121.6 nm) and the excited species emanating from the discharge are cocondensed with the molecules under investigation. The success of the method is demonstrated by the spectra shown in Figure 1. Here the yields of the *p*-dichlorobenzene cation using standard UV–visible or ‘windowless’ vacuum UV photolysis are contrasted. The latter approach is shown to produce an enormously enhanced yield.

X-ray irradiation is another good way to produce radicals in low-temperature solids. To take just one example, the methoxyl radical MeO• is generated by X-ray irradiation of solid methanol-*d*<sub>1</sub> at 4.2 K:

It has been the view of many chemists that ionizing radiation represents a ‘sledgehammer’ that will break molecules indiscriminately into a wide variety of products. However, it has become increasingly apparent that, for properly controlled systems, the products are often simpler and more readily predictable than those formed by UV light. Thus  $\gamma$ -rays may be used to produce a wide range of radicals and ions

**Figure 1** UV–visible absorption spectra of matrix-isolated *p*-dichlorobenzene and of its radical cation: (a) spectrum of *p*-dichlorobenzene before photolysis; (b) spectrum after 15 min photolysis at = 220–1000 nm; (c) spectrum after 15 min Ar resonance photolysis. The much increased yield of product upon vacuum UV photolysis can clearly be seen. (Reprinted with permission from Friedman *et al.*, *J. Phys. Chem.*, 1984, **88**, 1944. © 1984 American Chemical Society)

(equation 5 for example).

The ‘freon’ CFCl<sub>3</sub> is used as the solid host here since it has an ionization potential of ca. 11.8 eV, while the ionization potential of Me<sub>2</sub>Te is 7.9 eV. Thus ionization of the guest is favored over that of the host.

### 3 METHODS OF DETECTION OF SHORT-LIVED INTERMEDIATES

This section addresses the question: how is it possible to obtain spectra of species whose lifetimes are only a small fraction of a second? It is only within the past 60 or so years that direct observation of short-lived molecules has been possible.

Nowadays such studies are relatively commonplace and three quite distinct methods are typically used: (i) flow techniques, (ii) flash photolysis, and (iii) matrix isolation. The oldest of these approaches is the flow method developed independently in the 1920s by Paneth, for demonstrating the existence and reactivity of gaseous free radicals, and by Hartridge and Roughton, for studying biochemical liquid-phase processes. Flash photolysis was first reported by Norrish and Porter in 1949, while matrix isolation, an invention of George Pimentel, was first used in 1953. To complement these methods, brief mention is made of two approaches that allow the presence of a reactive intermediate to be inferred without direct observation. These are (i) kinetic measurements and (ii) chemical trapping experiments, where a reagent is added to the reaction mixture, which forms a stable product with the intermediate and which is particularly characteristic of that intermediate.

### 3.1 Flow Techniques

If an unstable species is generated continuously in a flow system, its decay establishes steady-state concentrations that decrease with distance downstream from the point of generation. It is thus possible to detect spectroscopically the unstable intermediate, though, of course, the spectra will necessarily be complicated by the presence of unreacted reagents or carrier material. Flow methods may be used to look at unstable species in the gas phase or in solution. They are ideally suited to kinetic measurements since, if the velocity of the flow of gas or liquid is known, it is possible to measure the rate of decay of the species under investigation. Early experiments used UV–visible absorption or emission to monitor the species in the flow; however, such methods give only limited structural data. A more modern innovation is the use of tunable IR lasers to obtain high-resolution vibrational spectra.

Flow systems lend themselves to several other methods of detection. Radicals such as  $\text{Me}\cdot$  or  $\text{MeO}\cdot$  have been studied by flowing them through the cavity of an ESR spectrometer. The deflection of a beam of molecules in an electric field may give information about any permanent *Dipole Moment* of the species under investigation. Mass spectrometric detection and even structural measurements by gas electron diffraction may be made on the vapor.

It is pertinent to consider briefly the supersonic molecular beam. Here, a flow of gas is expanded through a nozzle into a vacuum in such a way that the flow diverges and becomes supersonic. As the gas expands, so the temperature falls, thus molecules within the beam may be studied at very low temperatures and essentially free from molecular interactions.

### 3.2 Flash Photolysis

If a short-lived species is suddenly generated in a nonflowing sample it is possible to monitor the species

**Figure 2** (a) An arrangement for nanosecond flash photolysis. (b) A schematic diagram of a matrix-isolation apparatus

spectroscopically some time after its generation, but before its decay is complete, provided that a very fast detection technique is available. Early systems used high-intensity UV lamps to generate the species and UV–visible spectroscopy to monitor their decay. Modern flash photolysis experiments generally use lasers. An arrangement for ‘nanosecond’ flash photolysis is shown schematically in Figure 2(a). In this case one laser only is used. Light from the laser initiates photolysis but some light is directed by means of a beam splitter to a vessel containing a fluorescent solution. Fluorescence from the solution gives a continuum of light over a region of the visible spectrum and this is used as the spectroscopic source for monitoring the decay of the reaction intermediates. It is possible to use a second (normally tunable) laser for this purpose. An IR

laser can be used; thus it is possible to build up point-by-point IR spectra of the intermediates. However, the process is laborious. A large number of points are needed to cover even a relatively small part of the spectrum such as the  $\nu(\text{CO})$  region.

### 3.3 Matrix Isolation

This technique consists of trapping reactive molecules in a cold, solid, inert environment, where bimolecular reactions are prevented (provided that the sample is at sufficiently high dilution) and where the low temperatures greatly reduce the possibility of unimolecular decomposition.<sup>4</sup> In Figure 2(b) is shown a standard arrangement for a matrix-isolation apparatus. The low temperatures are often attained by the use of microrefrigerators using helium as the working fluid. The cold substrate, the nature of which depends upon the type of spectroscopy being used to monitor the sample, is enclosed in a shroud that is maintained at high vacuum.

Preparation of matrix-isolated samples generally follows one of two routes. Either the short-lived species is formed in the gas phase (by photolysis, pyrolysis, or the action of a discharge) then condensed with a large excess (typically thousandfold) of the matrix material, or a stable precursor is trapped within the matrix and the unstable species are generated in situ by photolysis or radiolysis.

Matrix isolation has the potential of tailoring the detection method to the problem. A large number of spectroscopic techniques are employed for matrix-isolated samples. Matrix isolation is thus an excellent method for studying the structures of short-lived molecules. However, it does have its drawbacks. Firstly, it can give no kinetic information. Secondly, the question must be asked: to what extent are species seen in a matrix analogous to those in more 'normal' chemical environments?

It is possible to address these points by studying reactive intermediates in low-temperature liquid solution, a typical solvent being liquid xenon. Here the molecules are retarded, rather than stopped so that, while conventional spectroscopic monitoring is possible, kinetic information about the species may also be obtained. In this way a 'bridge' is formed between flash photolysis work and matrix isolation.

## 4 STRUCTURAL INFORMATION FROM SPECTROSCOPIC MEASUREMENTS<sup>5</sup>

### 4.1 Nuclear Magnetic Resonance Spectroscopy

This technique is of immense potential importance but so far has been of very limited applicability towards short-lived intermediates. It is too slow for use in flash photolysis and there are extreme problems of sensitivity in matrix-isolation experiments. Although the feat of obtaining  $^1\text{H}$  and  $^{13}\text{C}$

nuclear magnetic resonance (NMR) spectra of stable matrix-isolated molecules was first achieved some time ago, it is only relatively recently that short-lived species have been detected in this way. Thus two-dimensional solid-state NMR has been used to study the intermediate 3,4-dimethylenethiophene (**4**) generated by photolysis of the parent diazo compound (**3**) in a 2-methyltetrahydrofuran glass at 77 K (equation 6).

It is not pertinent here to go into details of 2D NMR spectroscopy; such material is adequately covered elsewhere.<sup>6</sup> Suffice it to say that, in this instance, computer simulation of the dipolar coupled  $^{13}\text{C}$  sideband patterns allowed estimates to be made of the C–H bond distances and the H–C–H bond angles. Such information is of extreme importance. A great shortcoming of matrix isolation is the lack of *Bond Length* information. Two techniques have been developed that will give these data: one is NMR, the other is extended X-ray absorption fine structure (EXAFS) (see Section 4.6).

### 4.2 Electron Spin Resonance (ESR) Spectroscopy

*Electron Spin Resonance* (ESR) spectroscopy is a very powerful method for studying species with *unpaired electrons*. It has been used to investigate short-lived intermediates in flow systems and in matrices. The two main data of interest from an ESR Experiment are the *g* values and the hyperfine splittings. The latter are important in providing information about the delocalization of the unpaired electrons within the molecule. For an electron with some *s* character, coupling between electron and nuclear spin magnetic moments occurs by the so-called Fermi contact interaction. Coupling to a single nucleus with spin  $n/2$  gives  $n + 1$  lines that are of equal intensity and are equally spaced. Coupling to  $n$  equivalent nuclei of spin  $1/2$  again gives  $n + 1$  lines but here the intensities follow the binomial distribution. Low-temperature matrices are anisotropic systems; thus the situation is complicated in that both *g* values and hyperfine splitting constants must be considered as tensors. Three principal terms are obtained (for *g* values these may be labeled  $g_x$ ,  $g_y$  and  $g_z$ ). For systems with cubic or spherical symmetry these are equal; for those with at least axial symmetry there are two terms (labeled  $g_{\parallel}$  and  $g_{\perp}$ ); for lower symmetries all three terms are different. In Figure 3(a) is shown the ESR spectrum of the  $^{15}\text{N}_2\text{CO}^+$  cation in a neon matrix at 4 K, formed by the reaction of  $\text{CO}^+$  with  $^{15}\text{N}_2$ . Both parallel and perpendicular components can be seen: each forms a doublet of doublets, which points to the interaction of the unpaired electron with two inequivalent  $I = 1/2$   $^{15}\text{N}$  nuclei. Thus, the structure of the cation may be deduced as (**5**).

**Figure 3** (a) ESR spectrum of the cation  $^{15}\text{N}_2\text{CO}^+$  in a neon matrix at 4 K. (Reproduced by permission of the American Chemical Society from Knight Jr, *Acc. Chem. Res.*, 1986, **19**, 313) (b) ESR spectrum of pseudorotating  $^6\text{Li}_3$  in an argon matrix at 28.5 K. (Reproduced by permission of American Institute of Physics from Garland and Lindsay, *J. Chem. Phys.*, 1983, **78**, 2814)

Figure 3(b) shows the ESR spectrum of the trimer  $^6\text{Li}_3$  in an argon matrix at 28.5 K. Despite complications due to the presence of the heptamer  $^6\text{Li}_7$  and an unknown impurity  $^6\text{LiX}$ , seven equally spaced signals can be seen. These have the correct intensity ratio to belong to a molecule with three equivalent  $^6\text{Li}$  nuclei ( $I = 1$ ). It appears that the  $\text{Li}_3$  trimer is rapidly pseudorotating in an argon matrix at this temperature; thus the system behaves as an isotropic one and only one set of  $g$  values are seen.

In this brief discussion, only radicals that have just one unpaired electron are mentioned. Obviously there are many systems that have several unpaired electrons but, especially for anisotropic systems, the ESR spectra for such species can be extremely complicated. More information on aspects of ESR spectroscopy of short-lived intermediates is given in two excellent reviews on the subject.<sup>6,7</sup>

### 4.3 Rotational Spectroscopy

For short-lived molecules this technique is only really of use for flow systems, where tunable lasers are employed to record high-resolution spectra; thus rotational fine structure

can be seen. In Figure 4 is shown the high-resolution rotation–vibration spectrum, recorded using a tunable IR laser, of the Q-branch of the bending vibration of  $\text{FO}_2$  prepared in a flow tube reaction. The band is centered near  $578\text{ cm}^{-1}$  and the whole spectrum shown covers only  $1.5\text{ cm}^{-1}$ . Analysis of the rotational fine structure of electronic bands is also possible. Much information about unstable diatomic molecules has been derived in this way: the rotation constant of a diatomic molecule may be calculated for each of many vibrational states of each electronic state involved in the transition. Much less information has been forthcoming for larger molecules, in part because it is difficult to attain the resolution needed to observe rotational fine structure on an electronic band in these cases. More fundamentally, the fine structure is often not defined because the excited state has a very short lifetime, with a consequent uncertainty in energy levels due to the uncertainty principle. By their nature, solid matrices are not amenable to rotational spectroscopy for the simple reason that all but the smallest molecules cannot rotate within these rigid media.

The most important use of rotational spectroscopy is the determination of rotation constants. A problem besetting rotational spectroscopy is centrifugal distortion; however, it is possible to take account of this if precise data over a range of quantum numbers is available.

Having once obtained rotational constants it is possible to define molecular structures via the corresponding moments of inertia. Both bond lengths and bond angles can be obtained, but the process is not always straightforward and, for polyatomics, can be laborious; detailed descriptions of these procedures are given by Hollas.<sup>8</sup>

**Figure 4** The Q-branch of the bending vibration of  $\text{FO}_2$  prepared in a flow tube reaction. The band is centered near  $578\text{ cm}^{-1}$  and the whole spectrum shown covers only  $1.5\text{ cm}^{-1}$ . (Reproduced by permission of American Institute of Physics from Yamada and Hirota, *J. Chem. Phys.*, 1984, **80**, 4694)

*Isotopic* substitution may help us to obtain rotation constants. It also allows us to define atom positions within a molecule precisely (the effect of change of mass is small if the substituted atom is close to the center of mass, and zero if it is at the center of mass, for example, the rotation constants of  $\text{BCl}_3$  are unaffected by the boron isotopic mass), and may confirm the presence of a particular type of atom in the molecule. This latter point is of particular value in studying unstable species where elemental analysis is impracticable. For example, in order to prove that a species under investigation is an oxide we may observe a shift in the position of rotational lines when  $^{18}\text{O}$  replaces  $^{16}\text{O}$ .

#### 4.4 Vibrational Spectroscopy

Over the years, infrared (IR) absorption spectroscopy (*see Infrared Spectroscopy*) has been one of the mainstays of matrix isolation and it is nowadays being used increasingly (utilizing IR lasers) for monitoring the intermediates of flash photolysis reactions.

The main information to be obtained from IR spectroscopy concerns the presence of various groups within a molecule. Thus the presence of a nonclassically bound  $\eta^2\text{-H}_2$  group in the complex  $\text{H}_2\text{Cr}(\text{CO})_5$  in low-temperature liquid xenon solution may be demonstrated by the presence of an IR band at ca.  $3020\text{ cm}^{-1}$  corresponding to the  $\nu(\text{H-H})$  vibration.<sup>9</sup> Since the number of IR active vibrations depends upon the symmetry of the molecule under investigation, it is also possible to learn much about the number and geometry of groups within the molecule by analysis of the IR spectrum. A classical example is provided by matrix-isolated metal carbonyl fragments. Thus, for example, it should be straightforward to distinguish between  $C_{2v}$  (6) and  $D_{4h}$  (7) (*Square Planar*) symmetries for an  $\text{M}(\text{CO})_4$  fragment, since the former should show four IR active  $\nu(\text{CO})$  modes and the latter only one. However, the most unambiguous results are obtained when isotopic substitution is employed. For metal carbonyls partial enrichment in  $^{13}\text{CO}$  is normally used, so that all isotopomers

of the type  $\text{M}(^{12}\text{CO})_x(^{13}\text{CO})_{n-x}$  are produced. For low values of  $n$  it is a relatively easy matter to determine the identity of the  $\text{M}(\text{CO})_n$  fragment from the spectra of the isotopic species. The molecule chromyl carbonyl,  $\text{O}_2\text{Cr}(\text{CO})_2$  (8), has a nonlinear  $C_{2v}$   $\text{Cr}(\text{CO})_2$  fragment. Thus, the IR spectrum of the molecule, when enriched 50% in  $^{13}\text{CO}$ , shows two triplets of bands each with a 1:2:1 intensity ratio, corresponding to the symmetric and antisymmetric  $\nu(\text{CO})$  modes of the  $\text{Cr}(^{12}\text{CO})_2$ ,  $\text{Cr}(^{12}\text{CO})(^{13}\text{CO})$ , and  $\text{Cr}(^{13}\text{CO})_2$  isotopomers.<sup>10</sup>

For more complex examples, it is necessary to model the IR spectrum using different possible geometries for the  $\text{M}(\text{CO})_n$  fragment and estimated stretching and interaction force constants. If the  $\text{M}(\text{CO})_n$  fragment has high symmetry, the results are usually unambiguous, for example, the square planar structure of the  $\text{Mo}(\text{CO})_4$  fragment of *trans*- $\text{O}_2\text{Mo}(\text{CO})_4$  (9) is clear from the results of  $^{13}\text{CO}$  substitution.<sup>11</sup> For this experiment, different degrees of  $^{13}\text{CO}$  enrichment (33, 55, and 65%) were used. As shown in Figure 5, the spectra obtained can clearly be used to distinguish between a  $D_{4h}$   $\text{M}(\text{CO})_4$  and  $D_{3h}$   $\text{M}(\text{CO})_3$  fragments, either of which geometries would account for the IR spectrum of the unenriched molecule. For less symmetric species, unambiguous results may be obtained, though here it is necessary to pay careful attention to the matching of both the intensities and positions of peaks in the observed and calculated spectra.

Bond angles may be calculated from IR spectra in two distinct ways: (i) intensity measurements and (ii) isotopic shift calculations. For a molecule such as  $\text{O}_2\text{Cr}(\text{CO})_2$  (8), it is a relatively simple matter to calculate the C–Cr–C bond angle

**Figure 5** Stacked plot showing observed and predicted IR absorption spectra for *trans*-O<sub>2</sub>Mo(CO)<sub>4</sub> in the region 2068–2080 cm<sup>−1</sup> upon 33, 55, and 65% <sup>13</sup>CO enrichment: (a) predicted spectrum assuming a *D*<sub>3h</sub> Mo(CO)<sub>3</sub> moiety; (b) observed spectrum; (c) predicted spectrum assuming a *D*<sub>4h</sub> Mo(CO)<sub>4</sub> moiety. ( $\theta$ ). If we assume that there is no coupling between  $\nu(\text{CO})$  and any other vibration in the molecule, then we may estimate the bond angle from measured intensities of the bands arising from the symmetric and antisymmetric carbonyl stretching fundamentals using the relationship

$$\frac{I_{\text{sym}}}{I_{\text{asym}}} = \tan^2(\theta/2) \quad (7)$$

Nor is it difficult to modify this procedure to take account of the motion of a central atom, for example, to estimate the Mn–O–Mn bond angle ( $\theta$ ) of the O-bridged molecule Mn<sub>2</sub>O<sub>7</sub>. Here  $\theta$  is calculated from the intensities of symmetric and antisymmetric  $\nu(\text{Mn–O–Mn})$  fundamentals using the relationship

$$\frac{I_{\text{asym}}}{I_{\text{sym}}} = \tan^2(\theta/2) \left[ \frac{(m(\text{O}) + 2m(\text{Mn}) \sin^2(\theta/2))}{(m(\text{O}) + 2m(\text{Mn}) \cos^2(\theta/2))} \right] \quad (8)$$

where  $m(\text{O})$  and  $m(\text{Mn})$  are the atomic masses of oxygen and manganese, respectively. For Mn<sub>2</sub>O<sub>7</sub>, this value will be somewhat inaccurate because of coupling between bridging and terminal  $\nu(\text{Mn–O})$  vibrations. It is also rendered somewhat inaccurate by the anharmonicity of the vibrations involved.

This last point is emphasized if we rely upon shifts in peak position upon isotopic substitution to calculate bond angles. It is possible to calculate the A–B–A bond angle of a molecule A<sub>2</sub>B by isotopic substitution of either A or B. In Figure 6 is shown the IR spectrum arising from the antisymmetric  $\nu(\text{MoO}_2)$  vibration of matrix-isolated (**9**), ca. 45% enriched in <sup>18</sup>O<sub>2</sub>. The isotopic splittings due to the natural abundance of the isotopes of Mo and due to <sup>16</sup>O<sub>2</sub> and <sup>18</sup>O<sub>2</sub> can be seen. It is possible to calculate O–Mo–O bond angles from either isotope splitting assuming that the O–Mo–O group behaves as

**Figure 6** The 780–720 cm<sup>−1</sup> of the IR absorption spectrum of *trans*-O<sub>2</sub>Mo(CO)<sub>4</sub>. The two bands are assigned to  $\nu_{\text{as}}(^{16}\text{O}=\text{Mo}=\text{O})$  and  $\nu_{\text{as}}(^{18}\text{O}=\text{Mo}=\text{O})$ . Both clearly exhibit Mo isotope structure. (Reprinted with permission from Ref. 11a © 1984 American Chemical Society)

an isolated harmonic triatomic oscillator. In fact, the observed frequencies are necessarily anharmonic. Thus, the isotopic substitution

gives an upper limit  $\theta_u$  for the bond angle from

$$\sin\left(\frac{\theta_u}{2}\right) = \left[ \frac{m(\text{Mo})\{m(^{16}\text{O}) - m(^{18}\text{O})R_1\}}{2(m(^{16}\text{O}))(m(^{18}\text{O}))(R_1 - 1)} \right]^{1/2} \quad (10)$$

where  $m(X)$  is the atomic mass of X and

$$R_1 = \left[ \frac{\nu(\text{Mo}^{18}\text{O}_2)}{\nu(\text{Mo}^{16}\text{O}_2)} \right]^2 \quad (11)$$

Similarly, the isotopic substitution

gives a lower limit,  $\theta_1$ , from

$$\sin\left(\frac{\theta_1}{2}\right) = \left[ \frac{(m(^x\text{Mo}))(m(^y\text{Mo}))(1 - R_2)}{2(m(\text{O}))(R_2(M(^y\text{Mo})) - m(^x\text{Mo}))} \right]^{1/2} \quad (13)$$

where

$$R_2 = \left[ \frac{\nu(^y\text{MoO}_2)}{\nu(^x\text{MoO}_2)} \right]^2 \quad (14)$$

As well as providing information on bond angles, isotopic substitution experiments may tell us about the mode of coordination of atoms within a molecule. Again the example taken is that of oxo species although, of course, the technique may as well be applied to other chemical entities. For oxo species it is necessary to distinguish between the modes of coordination (10), (11), and (12), where M = metal or other atom. Typically, (10) shows  $\nu(\text{O}-\text{O})$  in the region  $1000\text{--}1200\text{ cm}^{-1}$ , whereas  $\nu(\text{O}-\text{O})$  and  $\nu(\text{M}=\text{O})$  of (11) and (12), respectively, both occur in the typical range  $750\text{--}1000\text{ cm}^{-1}$ , at least when M is a transition metal. A clear distinction between (10), (11), and (12) may be made by enrichment of the molecules with  $^{18}\text{O}$ . Structure (10) is easily distinguished since two IR bands result from  $\nu(\text{O}-\text{O})$  of the mixed  $^{16}\text{O}^{18}\text{O}$  isotopomers owing to the possibility of two distinct modes of coordination, that is,  $\text{M}-^{16}\text{O}-^{18}\text{O}$  and  $\text{M}-^{18}\text{O}-^{16}\text{O}$ . The IR spectra shown in Figure 7 illustrate this point for the molecule cyclopentadiene-*O*-oxide (14), formed when (13) is subjected to photolysis in a 10%  $\text{O}_2$ -doped  $\text{N}_2$  matrix. To distinguish between (11) and (12) is again more difficult. In principle, (12) should show two  $\nu(\text{M}=\text{O})$  absorptions but (11) should show only one  $\nu(\text{O}-\text{O})$  absorption. In practice, often only one  $\nu(\text{M}=\text{O})$  band is seen for (12) either because one feature is obscured, or because  $\nu_{\text{sym}}(\text{MO}_2)$  is weak owing to a wide  $\text{O}-\text{M}-\text{O}$  bond angle. When generated from a mixture of  $^{16}\text{O}_2$ ,  $^{16}\text{O}^{18}\text{O}$ , and  $^{18}\text{O}_2$ , however, the absorption associated with  $\nu(\text{O}-\text{O})$  of (11) takes the form of a single symmetrical triplet; under similar circumstances, (12) is expected to display one or two unsymmetrical triplets, derived from the antisymmetric and symmetric  $\text{MO}_2$  stretching fundamentals. The unsymmetrical pattern results from strong coupling between the two stretching modes of the  $^{16}\text{O}=\text{M}=\text{O}$  unit since the reduction in local symmetry allows mixing between the two stretching vibrations

**Figure 7** IR spectra recorded after photolysis of diazocyclopentadiene in  $\text{O}_2$ -doped  $\text{N}_2$  matrices: (a)  $^{16}\text{O}_2$  and  $^{18}\text{O}_2$  present; (b)  $^{16}\text{O}_2$ ,  $^{16}\text{O}^{18}\text{O}$  and  $^{18}\text{O}_2$  present. that otherwise (on symmetry grounds) cannot mix. The effect is illustrated schematically in Figure 8.

It is always desirable to back up IR absorption spectroscopy with *Raman* measurements. The different selection rules for the two techniques means that, at least for symmetric species, it is often necessary to have data from both types of measurement to have a full picture of the vibrational spectrum. Raman spectroscopy has been used to study many matrix-isolated species although there are problems regarding intensity and photosensitivity. An excellent review exists on the subject that highlights both the applications and difficulties of the method.<sup>12</sup> A molecule that has been well characterized by both IR and Raman spectroscopy is the matrix-isolated species  $\text{Mo}(\text{CO})_5(\text{N}_2)$  (15).<sup>13</sup> Spectra for (15) are illustrated

**Figure 8** Predicted  $^{18}\text{O}$  isotopic splitting patterns in the IR spectra of (a) the  $\nu(\text{O}-\text{O})$  band of a dioxygen complex and (b) the symmetric and antisymmetric  $\nu(\text{M}=\text{O})$  bands of a bent dioxometal complex assuming a scrambled 1:2:1  $^{16}\text{O}_2$ ,  $^{16}\text{O}^{18}\text{O}$ ,  $^{18}\text{O}_2$  mixture ( $\text{O} = ^{16}\text{O}$ ,  $\bullet = ^{18}\text{O}$ )

in Figure 9. From the coincidence of the two  $a_1$   $\nu(\text{CO})$  modes (assigned to the  $a_1$  symmetry class on the basis of polarization studies on the Raman lines) and the noncoincidence of the other two  $\nu(\text{CO})$  features,  $C_{4v}$  symmetry was assigned to the molecule, implying the structure (15) with a linear Mo–N–N unit.

**Figure 9** (a) Raman and (b) IR spectra of matrix-isolated  $\text{Mo}(\text{CO})_5(\text{N}_2)$ . The peaks drawn as dashed lines are due to unreacted  $\text{Mo}(\text{CO})_6$ . (Reprinted with permission from Ref. 13 © 1978 American Chemical Society)

## 4.5 Electronic Spectroscopy

Electronic spectroscopy (*see Electronic Spectroscopy*), in one form or another, has been the principal method used for the detection of short-lived intermediates. UV–visible absorption was the initial spectroscopic method used with flash photolysis and flow systems, and for each of these methods it remains the most commonly used approach. For species in low-temperature matrices, many varieties of electronic spectroscopy have been used. These include UV–visible absorption and emission, fluorescence, magnetic circular dichroism (MCD) and magnetic linear dichroism, and photoelectron spectroscopy. It is unfortunate, therefore, that in many cases electronic spectroscopy yields little or no structural information. The exceptions are high-resolution spectra, where vibrational or rotational fine structure may be seen.

## 4.6 Extended X-ray Absorption Fine Structure (EXAFS)

EXAFS (*see Extended X-ray Absorption Fine Structure*) has been used to study a number of matrix-isolated species. EXAFS occurs when an X-ray photon with sufficient energy is absorbed by an atom so that a core electron is ejected. This electron may be represented as an outgoing spherical wave originating at the absorbing atom. If the atom has neighbors, backscattering from them causes interference with the outgoing wave. The outcome is that there are variations in the absorption coefficient that depend on the spatial relationship of the central atom and its neighbors. Thus, by measuring the EXAFS spectrum it is possible to measure bond distances and angles around the central atom. The EXAFS experiment involves measuring the absorption spectrum in the vicinity of the absorption edge for the chosen element. Almost universally, synchrotron radiation is used as the source. EXAFS has been used to study various matrix-isolated metal clusters; the first example of a combined in situ Fourier transform infrared (FTIR) and EXAFS study of a matrix-isolated molecule was reported for dibromomethane, ( $\text{CH}_2\text{Br}_2$ ). This work has now been extended to a number of metal carbonyl halide and other molecules.<sup>14</sup> In Figure 10 is given the EXAFS spectrum and Fourier transforms for  $\text{FeCl}_2$  isolated in solid CO; the observed curves are compared with calculated curves for the molecule *trans*- $\text{Fe}(\text{CO})_4\text{Cl}_2$  (16). A very good fit is obtained; thus bond lengths may be calculated: Fe–C, 1.85(3) Å Fe–O, 2.96(4) Å; Fe–Cl, 2.25(3) Å. As with NMR, the allure of this method lies in deriving of bond lengths for matrix-isolated species.

**Figure 10** (a) EXAFS spectrum and (b) Fourier transforms for  $\text{FeCl}_2$  isolated in solid CO: (—) experiment; (· · ·) curved wave multiple scattering theory for  $\text{trans-Cl}_2\text{Fe(CO)}_4$ . (Reprinted with permission from Ref. 14. © 1992 American Chemical Society)

#### 4.7 Mössbauer Spectroscopy

Mössbauer spectroscopy (*see Mössbauer Spectroscopy*) has been used to look at a number of matrix-isolated species. However, the absence of structural information makes it appropriate to combine Mössbauer spectroscopy with other methods. Peden *et al.* report combined IR and Mössbauer spectra for the products of condensing iron vapor with CO:  $\text{Fe(CO)}_x$  ( $x = 1-5$ ) and  $\text{Fe}_2(\text{CO})_y$  ( $y = 8$  or  $9$ ). The Mössbauer spectra also reveal the presence of unreacted iron atoms in the solid CO, which, of course, cannot be seen in IR absorption.

#### 4.8 Quantum Calculations

Most current matrix-isolation studies involve the use of computational calculations to back up experimental results. It is beyond the scope of this chapter, however, to discuss these in any detail. Such calculations, typically using *ab initio* methods although sometimes adopting the density functional approximation, are used not only to model stable molecules, but also short-lived intermediates and transition states. In this way calculations may provide information about molecules and reactions that is impossible to obtain through experiment alone. In other cases calculations are used to back up, or confirm experimental findings. Typically geometries, energies and vibrational frequencies and intensities are calculated for a

species of interest. A number of specific examples are quoted in the following sections of this chapter.

### 5 PHOTOCHEMISTRY OF TRANSITION METAL CARBONYLS

It is not surprising that transition metal carbonyls rank amongst the most well-studied of photochemical reactants (*see Photochemistry of Transition Metal Complexes: Theory*). They are almost ideal candidates for such work since they have high quantum yields for photochemical reactions (in particular for substitution of carbonyl groups). They also show UV absorptions with large extinction coefficients and are strong IR absorbers and Raman scatterers (especially in the  $1600-2200\text{ cm}^{-1}$  region, associated with CO stretching fundamentals), so that electronic and vibrational spectroscopy can readily be applied to monitor reactions of these molecules. Moreover they are generally volatile and readily soluble in nonpolar solvents so that sampling is rarely a problem.

There are very many known photochemical reactions of metal carbonyls; two classic examples are the substitution of a CO group by a donor ligand, for example, a

phosphine:

and the deposition of solid  $\text{Fe}_2(\text{CO})_9$  when solutions of  $\text{Fe(CO)}_5$  are irradiated:

Some of the earliest systematic studies of related reactions were carried out in the early 1960s by Sheline and his coworkers at Florida State University. They studied the replacement of carbonyl groups of metal carbonyls by electron donor and  $\pi$ -acceptor molecules; a further aim was to develop an understanding of the mechanism of such reactions. They found that exposure to UV light of a colorless solution of  $\text{W(CO)}_6$  in *n*-hexane containing acetonitrile resulted in the solution turning bright yellow almost immediately. At the same time, new IR absorptions in the  $1700\text{--}2200\text{ cm}^{-1}$  region appeared that could be assigned to the molecules  $\text{W(CO)}_5(\text{MeCN})$ ,  $\text{W(CO)}_4(\text{MeCN})_2$ , and  $\text{W(CO)}_3(\text{MeCN})_3$ . Not surprisingly, the distribution of these products was affected by the time of photolysis. After 20 s,  $\text{W(CO)}_5(\text{MeCN})$  was the principal product and only a low yield of  $\text{W(CO)}_3(\text{MeCN})_3$  was seen. The yield of  $\text{W(CO)}_3(\text{MeCN})_3$  was increased substantially if the photolysis time was increased to 150 s. Perhaps more interesting is the observation that  $\text{W(CO)}_6$  is regenerated if the photolyzed solution is allowed to stand unphotolyzed for 180 s. These workers postulated that the 16-electron intermediate  $\text{W(CO)}_5$  is involved in the reaction. However, other plausible interpretations are possible. Firstly, an associative or a dissociative mechanism could operate. Secondly, if a dissociative mechanism is preferred, it is conceivable that this could proceed via a radical or an ionic pathway. The observations of Sheline *et al.* provided circumstantial evidence in favor of the radical dissociative process. What was needed was firm evidence to establish the presence of the pentacarbonyl intermediate.

### 5.1 The Search for ‘Unsaturated’ Metal Carbonyl Molecules

Early experiments to search for the  $\text{Cr(CO)}_5$  molecule involved flash photolysis of cyclohexane solutions of  $\text{Cr(CO)}_6$  with UV–visible detection. Problems arose owing to impurities in the solvent interacting with unsaturated intermediates. Although some evidence was obtained for ‘naked’  $\text{Cr(CO)}_5$  it was not possible to confirm the existence of this species nor to distinguish between square pyramidal,  $C_{4v}$  (17), and trigonal bipyramidal,  $D_{3h}$  (18), geometries (*see Isomer, Types of*).

These findings indicate general difficulties in interpreting the results of flash photolysis experiments with UV–visible detection. First, no detailed structural information can be obtained. Second, minute traces of impurity in the solvent interfere strongly with the spectral behavior. It has now become clear that  $\text{Cr(CO)}_5$  (and other unsaturated carbonyls) are almost always complexed by solvent or matrix molecules or atoms. Even in a neon matrix there is some interaction to produce the species  $\text{Ne} \cdots \text{Cr(CO)}_5$ . ‘Naked’  $\text{Cr(CO)}_5$  can be made in the gas phase, and by some rather cunning time-resolved solution experiments. Here, solvated  $\text{Cr(CO)}_5$  is formed by UV photolysis of  $\text{Cr(CO)}_6$ , then the solvating molecule is removed by visible photolysis. Fast time-resolved spectroscopy allows the decay of the naked  $\text{Cr(CO)}_5$ , as it resolvates, to be monitored. It is clear that this decay is extremely rapid.

The use of tunable IR lasers means that nowadays structural information is more readily derived from flash photolysis experiments, and it is often of much interest to study molecular interactions of metal carbonyls in solution. It is now possible to make an estimate of the strengths of alkane  $\cdots \text{Cr}$  bonds in species such as  $(\text{CO})_5\text{Cr} \cdots \text{X}$  ( $\text{X}$  = alkane). Even neutral saturated metal carbonyls may show quite strong solvent interactions and such interactions may provide clues to any subsequent photochemical reactions. IR spectra have been obtained that provide strong evidence for intermolecular H-bonding between the 18-electron species  $[\text{Cp}^*\text{Ir(CO)}_2]$  and the sterically crowded fluoroalcohol  $(\text{C}_3\text{F}_7)(\text{CF}_3)_2\text{COH}$  in *n*-heptane solution (19).<sup>15</sup> A similar interaction might explain why O–H activation of MeOH is seen upon UV photolysis of cryogenic liquid xenon solutions of MeOH and  $[\text{Cp}^*\text{Ir(PMe}_3)_2\text{H}_2]$ .

It is still of much interest to consider the early experiments in which molecules such as  $\text{Cr(CO)}_5$  were studied in hydrocarbon glasses and inert gas matrices, since it is from these experiments that structural data on these species (albeit necessarily in their weakly solvated forms) was derived. IR detection of  $\text{M(CO)}_5$  ( $\text{M}$  = Cr, Mo, or W) molecules trapped

in a frozen hydrocarbon glass at 100 K showed three IR active  $\nu(\text{CO})$  absorptions whose relative intensities are indicative of  $C_{4v}$  symmetry (17) for the species. The effect of any possible distortion may be minimized by moving to a frozen inert gas matrix. In 1971, Graham, Poliakoff, and Turner published the results of experiments in which they succeeded in producing  $\text{M}(\text{CO})_5$  molecules by photolysis of  $\text{M}(\text{CO})_6$  in argon or methane matrices at 20 K. A pattern of IR bands corresponding to  $C_{4v}$  (17) symmetry for the molecules was again seen. A detailed analysis of the IR spectrum of  $\text{Cr}(\text{CO})_5$  produced on photolysis of randomly substituted  $\text{Cr}({}^{13}\text{CO})_x({}^{12}\text{CO})_{6-x}$  containing ca. 50%  ${}^{13}\text{CO}$  gave an accurate fit to a  $C_{4v}$  structure. From intensity data, axial–radial bond angles ( $\alpha$ ) of 90–95° were calculated.

Even in such an inert environment it soon became clear that the  $\text{M}(\text{CO})_5$  molecules are not completely free from interaction with the host material. On moving from a frozen hydrocarbon glass to a methane matrix the shifts in the position of the IR bands of  $\text{Cr}(\text{CO})_5$  are relatively modest (4–6  $\text{cm}^{-1}$ ). By contrast, quite a large shift in the position of the visible band of  $\text{Cr}(\text{CO})_5$  is seen upon changing the host material. This feature is centered at 489 nm when methane is employed as host, but shifts to 487 nm for xenon, 545 nm for argon, 560 nm for sulfur hexafluoride, and a high value of 624 nm for neon. In a mixed Ne/Xe matrix, two bands are seen, demonstrating that a specific interaction with each noble gas occurs since a generalized solvent effect would lead to a single absorption located somewhere between the positions of the absorptions in the pure matrices. Photochemical experiments show that a reversible photochromic reaction takes place (equation 17). It is presumed that neon has the weakest interaction with the metal carbonyl fragment and therefore that the situation in a neon matrix most closely resembles the gas phase.

It is possible to make naked  $\text{Cr}(\text{CO})_5$  in the gas phase. Pulsed laser excitation at 249 nm of  $\text{Cr}(\text{CO})_6$  vapor yields  $\text{Cr}(\text{CO})_5$  and CO. Time-resolved IR spectroscopy reveals that the structure of gaseous  $\text{Cr}(\text{CO})_5$  is the same as that adopted in a solid matrix, that is, (17). Thus, the square pyramidal structure for ground state  $\text{Cr}(\text{CO})_5$  is confirmed. Photons of wavelength 249 nm are sufficiently energetic to rupture more than one M–C bond. Thus, after only 0.5  $\mu\text{s}$ , the yield of  $\text{Cr}(\text{CO})_5$  decays and  $\text{Cr}(\text{CO})_4$  is seen as the principal product. If the wavelength of the exciting radiation is reduced to 193 nm then a high yield of  $\text{Cr}(\text{CO})_3$  is seen after 0.5  $\mu\text{s}$ . The gaseous molecules  $\text{Cr}(\text{CO})_4$  and  $\text{Cr}(\text{CO})_3$  are found to adopt  $C_{2v}$  (20) and  $C_{3v}$  (21) symmetries, respectively.

It is rather more difficult to generate high yields of the molecules  $\text{M}(\text{CO})_4$  and  $\text{M}(\text{CO})_3$  ( $\text{M} = \text{Cr}, \text{Mo}, \text{or W}$ ) in a

low-temperature matrix since energy transfer is much more efficient than in low-pressure gas-phase systems. Prolonged photolysis is required, but the molecules may be produced and isotopic studies using  ${}^{13}\text{CO}$  show that the structures of these molecules are the same as in the gas phase. For  $\text{Mo}(\text{CO})_4$ , the angles  $\beta$  and  $\beta'$  are calculated as 174° and 107°, respectively; for  $\text{Mo}(\text{CO})_3$   $\gamma = 105^\circ$ .

It is of interest to compare the structure of the  $d^6$  molecule  $\text{Mo}(\text{CO})_4$  with that of the  $d^8$  species  $\text{Fe}(\text{CO})_4$  generated by UV photolysis of matrix-isolated  $\text{Fe}(\text{CO})_5 \cdot {}^3\text{Fe}(\text{CO})_4$  also adopts  $C_{2v}$  symmetry with  $\beta = 150^\circ$  and  $\beta' = 120^\circ$ . A simple consideration of the d orbital splitting pattern for a  $d^8$  species of  $C_{2v}$  symmetry suggests the presence of two unpaired electrons; this hypothesis was proved by the experimental observation of a temperature-dependent MCD spectrum for  $\text{Fe}(\text{CO})_4$  (diamagnetic species do not show any temperature dependence of their MCD signals). Thus,  $\text{Fe}(\text{CO})_4$  is the first binary transition metal carbonyl shown to have a high-spin electronic ground state. An interesting point about the structures of these unsaturated metal carbonyls is that none of them are much distorted from the structures that would be obtained by selective removal of CO groups from an octahedron. It is possible that an overriding factor in determining these structures is the maximization of overlap between filled ligand orbitals and unfilled metal d orbitals (see *High-spin & Low-spin Compounds* and *Ligand Field Theory*).

Differences between matrix-isolation and gas-phase photochemistry become more distinct when dinuclear and trinuclear carbonyls are considered. For a simple metal–metal bonded dinuclear carbonyl such as  $\text{Mn}_2(\text{CO})_{10}$ , two primary photochemical steps are possible, namely M–CO dissociation or M–M bond rupture. In solution both processes occur, whereas in rigid media CO loss is seen as the sole discernible primary photolysis step, presumably because  $\text{Mn}(\text{CO})_5$  radicals readily recombine in the matrix cage. In argon matrices, photolysis of  $\text{Mn}_2(\text{CO})_{10}$  yields  $\text{Mn}_2(\text{CO})_9$ , a molecule with a semibridging carbonyl group (with  $\nu(\text{CO})$  at 1764  $\text{cm}^{-1}$ ) that is shown by polarization studies to lie at about 45° to the Mn–Mn axis (22). By contrast,  $\text{Re}_2(\text{CO})_{10}$  gives rise to two unbridged isomers of  $\text{Re}_2(\text{CO})_9$  with the CO vacancy in equatorial (23a) or axial (23b) positions. The two isomers may be interconverted by UV irradiation. In a similar vein,  $\text{M}_3(\text{CO})_{12}$  ( $\text{M} = \text{Fe}$  or  $\text{Ru}$ ) molecules, when trapped in methylcyclohexane glass at 90 K, show CO loss as the primary photolytic step, although the reaction sequence is complicated by the presence of different isomers of the photoproduct  $\text{M}_3(\text{CO})_{11}$ . By contrast, in hydrocarbon solution, photofragmentation of the cluster takes place. In fluid media, bimolecular reactions

involving large fragments may occur, which are prevented in rigid matrices. An example is provided by the formation of a species  $\text{Cr}_2(\text{CO})_{10}$  (whose structure remains unknown) upon photolysis of gaseous  $\text{Cr}(\text{CO})_6$ , presumably by a reaction of the type

The photochemistry of more complex carbonyls that contain ligands other than CO has been studied in some detail. Time-resolved IR spectroscopy has been used to study the photochemistry of the dinuclear carbonyl  $[\text{CpFe}(\text{CO})_2]_2$  (see *Cyclopentadienyl*) in solution and the results of these experiments have been compared with those obtained from earlier matrix-isolation work.<sup>16</sup>

In a  $\text{CH}_4$  matrix at 12 K, (24) yields, upon UV photolysis, the CO-bridged dimer (25). When (24) is subjected to flash photolysis in cyclohexane solution at room temperature, time-resolved IR studies show that both (25) and the mononuclear radical  $[\text{CpFe}(\text{CO})_2]$  are formed within 5  $\mu\text{s}$ . The radical has a half-life of <25  $\mu\text{s}$  while (25) has a half-life of 1.5 ms under the experimental conditions. If the cyclohexane solution is doped with the two-electron donor molecule MeCN it is possible to monitor the formation of the substitution product  $[\text{Cp}_2\text{Fe}_2(\text{CO})_3\text{L}]$  (L = MeCN) (equation 19).

Kinetic studies, as illustrated by the spectra in Figure 11, leave little doubt that the principal intermediate in the photosubstitution is not the radical but rather the dinuclear species (25). This situation is not true, however, for all ligands.

When the hydrocarbon solution is doped with the phosphine  $\text{P}(\text{OMe})_3$  in place of MeCN, a reaction with the radical is seen:

The different pathways are reflected by the magnitudes of the bimolecular rate constants at 25 °C: L = MeCN,  $k_2 \sim 7.6 \times 10^5 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ ; L =  $\text{P}(\text{OMe})_3$ ,  $k_2 \sim 8.9 \times 10^8 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . The latter value is only about one order of magnitude slower than the diffusion controlled limit. These studies show the value of time-resolved IR spectroscopy for obtaining kinetic data.

When the photochemistry of carbonyls that also contain ligands other than CO is considered, it is not always the case that loss of CO predominates as the principal reaction pathway. For example, irradiation of  $[\text{CpM}(\text{CO})_3\text{Et}]$  (M = Mo or W) generates  $[\text{CpM}(\text{CO})_3\text{H}]$  by loss of  $\text{C}_2\text{H}_4$  (see *Alkene Complexes*). Scheme 1 presents a plausible mechanism for this process, which has been studied in *n*-heptane solution by time-resolved IR spectroscopy and in low-temperature matrices. Two distinct dicarbonyl species (26) and (27) are seen. In a matrix, (26) and (27) may be interconverted by photolysis at selected wavelengths. The reaction then proceeds via cis and trans isomers of  $[\text{CpM}(\text{CO})_2(\text{C}_2\text{H}_4)\text{H}]$ . The results suggest that, in this system,  $\beta$ -hydrogen transfer is a facile process; they have important implications for the current interest in *agostic* hydrogen interactions.

**Figure 11** Time-resolved IR spectrum obtained after flash photolysis of  $[\text{CpFe}(\text{CO})_2]_2$  and MeCN in cyclohexane solution. Two intermediates, B =  $\text{CpFe}(\text{CO})_2$  and C =  $\text{CpFe}(\mu\text{-CO})_3$ , are seen. D is the reaction product  $\text{Cp}_2\text{Fe}_2(\text{CO})_3(\text{MeCN})$ . ## 5.2 Reactions of Unsaturated Metal Carbonyls with $\text{CO}$ , $\text{N}_2$ , and $\text{H}_2$

Unsaturated metal carbonyls are necessarily prone towards addition reactions. Thus 16-electron species such as  $\text{M}(\text{CO})_5$  ( $\text{M} = \text{Cr}, \text{Mo}, \text{or W}$ ) and  $\text{Fe}(\text{CO})_4$  will readily react with two-electron donor ligands. A large number of such reactions are known. Here details of three examples are considered, namely, the addition of  $\text{CO}$ ,  $\text{N}_2$ , and  $\text{H}_2$  molecules (*see Hydride Complexes of the Transition Metals*).

Sheline's early experiments showed that  $\text{M}(\text{CO})_6$  molecules could be regenerated when photolyzed solutions of the hexacarbonyl were left to stand. Matrix-isolated  $\text{M}(\text{CO})_6$  may be obtained from  $\text{M}(\text{CO})_5$  only by annealing or upon photolysis into the visible absorption band of the pentacarbonyl:

The mechanism of the photochemical reaction has been the subject of some elegant experiments involving polarized light both for photolysis and for spectroscopic measurements.<sup>17</sup> Unpolarized UV photolysis of  $\text{Cr}(\text{CO})_6$  in pure methane matrices yields randomly oriented  $\text{Cr}(\text{CO})_5 \cdots \text{CH}_4$  molecules. Polarized visible photolysis leads to specifically oriented  $\text{Cr}(\text{CO})_5 \cdots \text{CH}_4$  molecules, as evidenced by the development of linear dichroism in the visible absorption band. The direction of the spectral dichroism depends upon the direction of polarization of the irradiating beam (equation 22).

These experiments show that the matrix holds the  $\text{Cr}(\text{CO})_5$  fragment rigid at the beginning and end of the photolysis period, but that mobility is possible during irradiation. The most likely explanation is that visible photolysis causes the

$\text{Cr}(\text{CO})_5$  fragment to be excited from the ground state  $C_{4v}$  configuration to a  $D_{3h}$  excited state. The excited state can then relax back to a  $C_{4v}$  geometry, but reorientation of the molecule may occur (equation 23).

It is of course possible to propose a mechanism by which an  $\text{M}(\text{CO})_5$  fragment may take up a free  $\text{CO}$  molecule on visible photolysis to form  $\text{M}(\text{CO})_6$ . This is via photoreorientation causing the vacant site of  $\text{M}(\text{CO})_5$  to move around the molecule, such that it may be directed towards any adjacent  $\text{CO}$  molecule trapped within the matrix cage. In this way a chemical bond will be formed between  $\text{CO}$  and the  $\text{M}(\text{CO})_5$  fragment. Alternatively, if the vacant site of the final product is directed towards a methane molecule,  $\text{Cr}(\text{CO})_5 \cdots \text{CH}_4$  will be formed. This product is, however, still labile to visible photolysis, so reorientation may continue. Thus a reaction is possible with any  $\text{CO}$  molecule that is adjacent to the  $\text{M}(\text{CO})_5$  fragment. To backup this hypothesis it would be desirable to observe excited-state  $\text{Cr}(\text{CO})_5$  directly. Very recent solution experiments have been directed towards this end, but as yet such a species has defied unequivocal identification.

In a similar vein, near-IR photolysis of matrix-isolated  $\text{Fe}(\text{CO})_4$  promotes a reaction with photoejected  $\text{CO}$  to regenerate  $\text{Fe}(\text{CO})_5$ :

This finding led to an interesting study by Turner, Poliakoff *et al.* on the laser-induced isomerization of  $\text{Fe}(\text{CO})_4$ . A statistical mixture of the different isotopomers of  $\text{Fe}({}^{12}\text{C}^{16}\text{O})_{4-x}({}^{13}\text{C}^{18}\text{O})_x$  was formed in an argon matrix at 20 K by UV photolysis of matrix-isolated  $\text{Fe}(\text{CO})_5$

that had been 40% enriched with  $^{13}\text{C}^{18}\text{O}$ . These isotopomers are readily distinguished by their different IR absorption bands in the  $\nu(\text{CO})$  region. In all, there are seven possible isotopomers of  $\text{Fe}(\text{}^{12}\text{C}^{16}\text{O})_{4-x}(\text{}^{13}\text{C}^{18}\text{O})_x$ : two each of  $\text{Fe}(\text{}^{12}\text{C}^{16}\text{O})_{4-x}(\text{}^{13}\text{C}^{18}\text{O})_x$  and three of  $\text{Fe}(\text{}^{12}\text{C}^{16}\text{O})_{4-x}(\text{}^{13}\text{C}^{18}\text{O})_x$ . It was found that irradiation of the matrix with the output of a tunable IR laser at a frequency corresponding to one particular isotopomer promoted a selective rearrangement as shown in Scheme 2. These interconversions may clearly be described as pseudorotations but the results show that the permutational mode is not that expected for the normal *Berry Pseudorotation* seen, for example, in the thermal rearrangement of  $\text{SF}_4$ . Thus the isomerization of  $\text{Fe}(\text{CO})_4$  was the first reported example of a non-Berry pseudorotation.

Visible photolysis of  $\text{Mo}(\text{CO})_5$  trapped in matrices containing  $\text{N}_2$  results, not only in the regeneration of  $\text{Mo}(\text{CO})_6$ , but also in the formation of a dinitrogen complex  $\text{Mo}(\text{CO})_5(\text{N}_2)$  (Scheme 3).<sup>13</sup> This molecule has been characterized by IR and Raman spectroscopy. Studies involving isotopic substitution with  $^{15}\text{N}_2$ ,  $^{15}\text{N}^{14}\text{N}$ , and  $^{13}\text{CO}$  have confirmed that the molecule has  $C_{4v}$  symmetry and thus a linear  $\text{Mo}-\text{N}-\text{N}$  unit is implied (15). Similar reactions are known for  $\text{Cr}(\text{CO})_5$ ,  $\text{W}(\text{CO})_5$ ,  $\text{Fe}(\text{CO})_4$ , and  $\text{Ni}(\text{CO})_3$ .

**Scheme 2** Selective intramolecular rearrangement of isotopomers of  $\text{Fe}(\text{CO})_4$  partially enriched in  $^{13}\text{CO}$  via a non-Berry pseudorotation

**Scheme 3**

The photochemical reaction of the binuclear carbonyl  $\text{Re}_2(\text{CO})_{10}$  with  $\text{N}_2$  has been studied by matrix isolation. In an  $\text{N}_2$  matrix at 10 K,  $\text{Re}_2(\text{CO})_{10}$  yields  $\text{Re}_2(\text{CO})_9$  upon UV photolysis. When the matrix is annealed to 15–20 K the equatorial isomer  $\text{Re}_2(\text{CO})_9(\text{N}_2)$  (**28**) is generated by a bimolecular reaction. Irradiation of the matrix with visible light ( $\lambda = 546 \text{ nm}$ ) converts (**28**) to the axial isomer (**29**), while (**29**) can be reconverted to (**28**) on UV irradiation at 313 nm.

Although providing valuable structural information, such matrix experiments tell us little or nothing about the thermal stability of these dinitrogen complexes nor of the strength of the  $\text{M}-\text{N}$  bond. Experiments have sought to address this problem by looking at similar reactions in low-temperature inert solvents such as liquid xenon. It is shown that the molecule  $\text{Cr}(\text{CO})_5(\text{N}_2)$  survives at temperatures as high as  $-35^\circ\text{C}$ . For the related molecule  $\text{Ni}(\text{CO})_3(\text{N}_2)$ , kinetic studies of its dissociation have been possible, giving an estimate of about  $40 \text{ kJ mol}^{-1}$  for the activation enthalpy of the dissociative process:

Thus it is possible to estimate the enthalpy of the  $\text{Ni}-\text{N}$  bond (see *Bond Energies*).

The reactions between unsaturated metal carbonyls and dihydrogen have attracted much interest. Sweany discovered that a reversible interconversion between  $\text{Fe}(\text{CO})_4$  and  $\text{Fe}(\text{CO})_4\text{H}_2$  could be initiated by selective photolysis:

In this case, there is no reason to suppose that hydrogen is coordinated in any way other than the classical dihydride manner (**30**) (see *Hydrides: Solid State Transition Metal Complexes*). However, similar experiments using  $\text{Cr}(\text{CO})_5$  gave a product  $\text{Cr}(\text{CO})_5\text{H}_2$  for which strong circumstantial evidence pointed towards the nonclassical dihydrogen structure (**31**). Unfortunately, in low-temperature matrices

**Figure 12** IR spectra of  $\text{Cr(CO)}_6$  in hydrogen-doped liquid xenon solution: (a) before photolysis; (b) after photolysis in  $\text{H}_2$ -doped Xe; (c) after photolysis in  $\text{D}_2$ -doped Xe. the  $\nu(\text{H-H})$  mode was too weak to be observed. This problem was overcome by Poliakoff, Turner and coworkers who repeated the experiment in liquid xenon solution at 200 K.<sup>9</sup> Taking advantage of the long path length (27 mm) of their cell, they were able to obtain the spectra illustrated in Figure 12 in which the  $\nu(\text{H-H})$  vibration and its counterpart when  $\text{D}_2$  replaces  $\text{H}_2$  as reactant are clearly visible. Interest in such complexes continues. The Nottingham group have shown that photolysis of  $[\text{CpV(CO)}_4]$  in liquid xenon solution doped with  $\text{H}_2$  generates the nonclassical complex  $[\text{CpV(CO)}_3(\eta^2\text{-H}_2)]$ . By contrast, under similar conditions,  $[\text{CpTa(CO)}_4]$  yields a classical dihydride  $[\text{CpTa(CO)}_3(\text{H}_2)]$  while  $[\text{CpNb(CO)}_4]$  gives rise to a temperature-dependent equilibrium between the classical  $[\text{CpNb(CO)}_3(\text{H}_2)]$  and nonclassical  $[\text{CpNb(CO)}_3(\eta^2\text{-H}_2)]$  compounds. This equilibrium has been investigated by the use of time-resolved IR spectroscopy. Thus, we see a smooth trend where dihydrogen coordination is favored at the top of the group and the dihydride at the bottom.

The reactions of  $\text{M(CO)}_6$  ( $\text{M} = \text{Cr}, \text{Mo}$  or  $\text{W}$ ),  $(\eta^6\text{-C}_6\text{H}_3\text{Me}_3)\text{M(CO)}_3$  ( $\text{M} = \text{Cr}$  or  $\text{Mo}$ ) and  $\text{W(CO)}_5\text{CS}$  with  $\text{H}_2$  and  $\text{N}_2$  in polyethylene matrices have been investigated.<sup>17</sup> A high pressure (5000 lb in<sup>-2</sup>) and low-temperature (30 K)

cell was utilized to carry out these reactions, an approach that allows some of the advantages of ‘traditional’ matrix isolation to be combined with some of the advantages of low-temperature solution work. UV photolysis of  $\text{M(CO)}_6$  gives: under  $\text{N}_2$ ,  $\text{M(CO)}_5\text{N}_2$  and on prolonged photolysis  $\text{M(CO)}_{6-x}(\text{N}_2)_x$  ( $x = 2 - 4$ ); under  $\text{H}_2$ ,  $\text{M(CO)}_5(\eta^2\text{-H}_2)$ , and *cis*- $\text{M(CO)}_4(\eta^2\text{-H}_2)_2$  – the disubstituted products being previously unknown for  $\text{W}$  or  $\text{Mo}$ . One of the interesting features of this experimental arrangement is that the construction of the cell allows gases to be exchanged during a single experiment. Thus, thermal exchange between coordinated  $\text{N}_2$  and  $\text{H}_2$  ligands in  $\text{M(CO)}_5\text{L}$  compounds may be studied. It was found that the order of reactivity follows the sequence  $\text{Mo} > \text{Cr} > \text{W}$ . UV irradiation of  $(\eta^6\text{-C}_6\text{H}_3\text{Me}_3)\text{M(CO)}_3$  ( $\text{M} = \text{Cr}$  or  $\text{Mo}$ ) and  $\text{W(CO)}_5\text{CS}$  also leads to hitherto uncharacterized  $\text{N}_2$  and  $\text{H}_2$  complexes.

### 5.3 Photochemical Reactions of Metal Carbonyls with Dioxygen

UV irradiation of matrices containing  $\text{M(CO)}_6$  molecules ( $\text{M} = \text{Cr}, \text{Mo}$ , or  $\text{W}$ ) and  $\text{O}_2$  leads to the formation of oxocarbonyl species with fewer than five coordinated carbonyl groups that also contain, in one form or another, coordinated oxygen. Apparently the most stable oxocarbonyl molecule to be produced by photooxidation (*see Oxo Complex and Dioxygen & Related Ligands*) of matrix-isolated  $\text{Cr(CO)}_6$  is chromyl carbonyl (**8**).<sup>18</sup> The IR spectra of this species show clearly that the  $\text{O-O}$  bond has been cleaved. The  $\text{C-Cr-C}$  (from intensity measurements) and  $\text{O-Cr-O}$  (from  $^{16}\text{O}$ – $^{18}\text{O}$  isotopic shifts) bond angles are estimated at approximately  $118^\circ$  and  $129^\circ$ , respectively. This molecule attracts interest because it was the first example of a stable chromium(IV) carbonyl compound (*see Oxidation Number*), and yet it appears to be one of the most stable intermediates to be formed during photooxidation of  $\text{Cr(CO)}_6$ . The high energies of the  $\nu(\text{CO})$  vibrations ( $2125$  and  $2063\text{ cm}^{-1}$ ) reflect the minimal capacity of the metal center to engage in back donation to the  $\pi$ -antibonding (*see Back Bonding*) orbitals of the CO groups.

The discovery of chromyl carbonyl prompted a search for analogs of the other group 16 metals, namely molybdenum and tungsten. However, it was soon found that the photooxidation of  $\text{Mo(CO)}_6$  and  $\text{W(CO)}_6$  proceeds in a somewhat different manner. Here the molecules  $\text{O}_2\text{M(CO)}_2$  ( $\text{M} = \text{Mo}$  or  $\text{W}$ ) are seen in only low yield and the most abundant oxocarbonyl species seen are the previously unknown complexes *trans*-dioxotetracarbonylmolybdenum and *trans*-dioxotetracarbonyltungsten (**9**).<sup>11</sup> These species were characterized by IR and Raman spectroscopy, including isotopic substitution with  $^{13}\text{CO}$  and  $^{18}\text{O}$ . Crucial evidence for the *trans*  $\text{O=Mo=O}$  formulation came from the observed splitting of the  $\nu_{\text{as}}(\text{MoO}_2)$  IR absorption arising from the natural abundance of the different isotopes of molybdenum (see Figure 6).

For each of the group 16 hexacarbonyls, it is apparent that common to each reaction is an intermediate  $(\eta^2\text{-O}_2)\text{M}(\text{CO})_4$  (32). Upon UV photolysis the O–O bond is cleaved and CO groups are lost from the metal center yielding, upon prolonged photolysis, binary metal oxide molecules. Thus,  $\text{Cr}(\text{CO})_6$  yields as the final oxidation product  $\text{CrO}_2$ , while  $\text{Mo}(\text{CO})_6$  forms a mixture of  $\text{MoO}_2$  and  $\text{MoO}_3$ . The formation of binary tungsten oxides from  $\text{W}(\text{CO})_6$  is somewhat more complex. The final product is  $\text{WO}_3$  but this appears to be formed not from free  $\text{WO}_2$ , but rather from the molecule  $(\eta^2\text{-O}_2)\text{WO}_2$  by loss of an O atom:

On the basis of these matrix-isolation experiments, a more-or-less complete mechanism for the photooxidation of the binary carbonyls  $\text{M}(\text{CO})_6$  ( $\text{M} = \text{Cr}, \text{Mo}, \text{or W}$ ) in Ar matrices containing  $\text{O}_2$  at 20 K can be proposed (Scheme 4): (i) Cr,

544 nm, Mo 403 nm, W, 435 nm; (ii) Cr, W 367 nm, Mo 314 nm; (iii) Mo and W only, Mo 403 nm or anneal at 35 K, W anneal at 35 K; (iv) Cr 314 nm or anneal at 35 K; Mo, W 314 nm; (v) Cr and Mo only.

One distinctive feature of these photochemical reactions is the clear photoselectivity displayed. Thus, by using different wavelengths of light it is possible to build up the concentrations of individual species at the expense of others. For example, a high yield of the peroxo complex  $(\eta^2\text{-O}_2)\text{M}(\text{CO})_4$  (where  $\text{M} = \text{Mo}$  or  $\text{W}$ ) is generated upon visible (blue or green) photolysis, while near-UV photolysis promotes rupture of the O–O bond and loss of CO to form the dioxo species  $\text{O}_2\text{M}(\text{CO})_3$ .

Iron pentacarbonyl ( $\text{Fe}(\text{CO})_5$ ) may be photooxidized in a similar manner. Although no fewer than five distinct iron carbonyl intermediates are seen, there is no sign of any photoselectivity in this reaction sequence.<sup>18</sup> It is possible, however, to build up reasonable concentrations, at least of the early intermediates, by carefully controlling the time of photolysis. Hence, it appears that the first oxidation product is  $(\eta^2\text{-O}_2)\text{Fe}(\text{CO})_4$ , where the  $\text{O}_2$  ligand occupies a basal site in a square pyramidal framework (33).

Photolysis then proceeds by rupture of the O–O bond and loss of CO to generate  $\text{O}_2\text{Fe}(\text{CO})_3$ . Later oxocarbonyl intermediates are difficult to characterize since they are invariably formed only in meagre quantities. However, the nature of the final molecular binary oxide products does appear to have been resolved. They are the peroxo iron(II) species  $(\eta^2\text{-O}_2)\text{Fe}$  and the planar (or near planar) iron(VI) oxide  $\text{FeO}_3$ . Taken together the results point to the reaction scheme shown in Scheme 5 for the matrix photooxidation of  $\text{Fe}(\text{CO})_5$  in Ar or  $\text{CH}_4$  matrices containing  $\text{O}_2$  at 20 K.

Attention turned to the dinuclear carbonyls  $\text{Mn}_2(\text{CO})_{10}$ ,  $\text{Re}_2(\text{CO})_{10}$ , and  $\text{Co}_2(\text{CO})_8$ . Regarding mechanistic information, the study of  $\text{Re}_2(\text{CO})_{10}$  has been the most fruitful. Here two distinct oxocarbonyl species, which appear to contain only one rhenium atom each, are formed. The final product of the reaction is the O-bridged oxide  $\text{Re}_2\text{O}_7$ . In a similar vein,  $\text{Mn}_2(\text{CO})_{10}$  yields  $\text{Mn}_2\text{O}_7$  upon matrix photooxidation, although there is no hint of any intermediate in this process, no matter what steps are taken to produce such species. The photooxidation of  $\text{Co}_2(\text{CO})_8$  is likely to follow a pathway even more complex than that of  $\text{Mn}_2(\text{CO})_{10}$  or  $\text{Re}_2(\text{CO})_{10}$ . In this case not only is there competition between M–C and M–M bond rupture as the primary photochemical step, but there is also the complication of photoisomerism of the molecule.

### Scheme 5

Three isomers of  $\text{Co}_2(\text{CO})_8$ , one with CO bridges, have been identified in low-temperature matrices and these readily interconvert upon UV-visible photolysis. In the event, two mononuclear peroxocobalt carbonyls,  $(\eta^2\text{-O}_2)\text{Co}(\text{CO})_3$  (**34**) and  $(\eta^2\text{-O}_2)\text{Co}(\text{CO})_4$  (**35**), are formed; they have been identified by comparison of their IR spectra with those of the same products formed by cocondensation of Co atoms with mixtures of CO and  $\text{O}_2$ .

## 6 MAIN GROUP MOLECULES IN HIGH-TEMPERATURE VAPORS

## 6.1 Background

Many chemical molecules that are not stable under normal conditions at room temperature are found in high-temperature vapors. These include gaseous molecular forms of compounds such as metal oxides or chlorides that are normally encountered as solids at room temperature. Other species found in high-temperature vapors have unusual valencies and coordination numbers. Examples are the molecules  $\text{OPCl}$  and  $\text{O}_2\text{PCl}$ , which contain unusual two-coordinate trivalent and three-coordinate pentavalent phosphorus atoms, respectively. It is of interest to study such species to extend our knowledge of the structure and bonding of small molecules to new regions of the periodic table. Moreover, many such species are proposed chemical reaction intermediates.

Some methods of characterization of high-temperature molecules rely on direct flow-system vapor-phase measurements, for example, mass spectrometric and electron diffraction studies. Matrix isolation also plays a significant role in that vapor species may be trapped by rapid quenching. The most unambiguous results have perhaps been drawn from a combination of the two approaches.

## 6.2 Group 13

Monovalent compounds of the higher members of group 13 tend not to be stable. However, such species have been proposed as reaction intermediates (*see Aluminum: Inorganic Chemistry* and *Boron Hydrides*). Thus, the reaction, discovered by Alfred Stock, in which  $\text{B}_2\text{Cl}_4$  may be produced by the zinc discharge reduction of  $\text{BCl}_3$ , is believed to proceed via the intermediacy of  $\text{BCl}$ , which *inserts* into a B–Cl bond of a second  $\text{BCl}_3$  molecule:

Similarly, higher boron subhalides (e.g. the pale-yellow tetrahedral molecule  $\text{B}_4\text{Cl}_4$ , the yellow–orange  $\text{B}_9\text{Cl}_9$ , and the red  $\text{B}_9\text{Br}_9$ ) may be built up in discharge reactions of  $\text{BCl}_3$  or  $\text{BBr}_3$ , presumably again via  $\text{BCl}$  or  $\text{BBr}$  molecules, although the exact reaction mechanisms remain obscure. Monovalent molecules akin to  $\text{BCl}$  are stable in high-temperature vapors; they may be studied by gas-phase or matrix-isolation methods. Particularly well-studied are the aluminum monohalides.

These molecules can be generated in a variety of chemical systems. Thus,  $\text{AlCl}$  is formed when  $\text{Al}$  vapor, at about 1000 K, is allowed to react with  $\text{AlCl}_3$  vapor, at about 350 K,<sup>19</sup> while  $\text{AlBr}$  may be generated in a number of ways, for example,

Aluminum monofluoride is formed by the reaction of Al vapor with HF at 1100 K. All of these molecules have been studied in both the gas-phase and in low-temperature matrices. It is found that the neon matrix gives IR spectra that most closely resemble those obtained from the gas phase.

These monohalide molecules are prone to aggregation in matrices; thus cyclic dimers such as (36) are formed. Two possible routes available to monovalent Al molecules to achieve the more stable trivalent state are addition of a two-electron donor, or insertion into a two-electron bond. Unsurprisingly, therefore, AlF reacts with O atoms in a matrix to form the linear molecule OAlF, a product that is itself prone to dimerization, forming (37). The structures of (38) and (37) have been investigated by isotopic substitution experiments involving  $^{18}\text{O}$  and also by theoretical calculations. The structure of (38) is similar to that adopted by the stable solid  $(\text{SAI}\text{Cl})_2$  (39), which is formed when  $\text{AlCl}_3$  and  $\text{Al}_2\text{S}_3$  are heated together at around 600 K:

An example of an insertion reaction of an aluminium monohalide (cf. the insertion reactions of BCl mentioned earlier) is provided by the formation of planar  $\text{HAICl}_2$  (40) from  $\text{AlCl}$  and  $\text{HCl}$  in a low-temperature matrix. Similarly,  $\text{GaCl}$  will insert into  $\text{HCl}$  or  $\text{H}_2$  to form the matrix-isolated chlorogallanes  $\text{HGaCl}_2$  and  $\text{H}_2\text{GaCl}$ , respectively.

Aluminum monochloride may be generated in sufficient quantities to be used on a preparative scale. Cocondensation of  $\text{AlCl}$  vapor and dimethylacetylene at 77 K leads, upon warming the mixture to room temperature,<sup>20</sup> to the formation of an air- and moisture-sensitive product. This product shows an Al:Cl ratio of 1:1 while mass spectrometry suggests a molecular formula of  $\text{Al}_4\text{Cl}_4\text{C}_{16}\text{H}_{24}$ . A room-temperature single crystal X-ray diffraction study reveals the nature of the product. It consists of two dimeric 1,4-dialumina-2,5-cyclohexadiene rings (41) joined by a  $\pi$ -interaction between the Al atoms of one ring and the  $\text{C}=\text{C}$  bonds of the other (42). The  $\text{C}=\text{C}$  bonds are somewhat longer (136.7 pm) than an uncoordinated  $\text{C}=\text{C}$

bond, while the mean Al–C distance of 235.4 pm is approximately 10% greater than the Pt–C distance in the well-known alkene complex *Zeise's Salt*,  $\text{K}[\text{Pt}(\text{C}_2\text{H}_4)\text{Cl}_3]$ . The product is of interest as it might well be akin to intermediates in reactions of organoaluminum compounds; perhaps even in polymerization reactions catalyzed by Ziegler–Natta catalysts.

Interest in the reactions of monovalent aluminium compounds in low-temperature matrices has continued. Monomeric  $\text{AlCl}$  reacts, upon photoactivation, with acetylene in an argon matrix via insertion to give the acetylide species  $\text{Cl}(\text{H})\text{AlCCH}$ .<sup>21</sup> IR spectroscopy with isotopic substitution was used to identify the product. This work provides an example of the use of quantum chemical calculations in probing the structure of unstable matrix-isolated compounds. Since the early 1990s almost all experimental matrix-isolation studies have been backed up by quantum calculations. These are used to predict structures of reactive species and to calculate minimum energies for these structures. Calculations may also be used to predict the IR spectrum of a particular species such that observed and calculated spectra may be compared. The work quoted here<sup>21</sup> is one example taken from many, but the principles of using experiment and calculation together are demonstrated. The energies of the acetylide product and of an alternative cyclic species are calculated, as are IR spectra for the species. As may be seen from Figure 13, there is an excellent match between the observed and calculated spectra. The work also illustrates the point that calculations do not replace experimental findings. It is still necessary to carry out isotopic substitution experiments and to compare observed and calculated IR spectra for the various isotopomers of the proposed product. This approach has been extended to the more complex reaction between photoactivated  $\text{AlCl}$  and 2-butyne; here two products are seen that are believed to be the insertion product  $\text{Cl}(\text{H})\text{AlCH}_2\text{CCCH}_3$  and the cyclic alumina-cyclopropene isomer.<sup>21</sup> In a similar vein,  $\text{AlF}$  reacts with  $\text{O}_2$  in an argon matrix to give peroxy and bis-superoxy complexes of aluminium, that is,  $\text{FAIO}_2$  and  $\text{FAIO}_4$ .<sup>22</sup> The IR spectra shown in Figure 14 illustrate very nicely the importance of isotopic substitution in investigating systems such as this. It may be seen that when prepared from a mixture of  $^{16}\text{O}_2$  and  $^{18}\text{O}_2$   $\text{FAIO}_2$  shows a doublet of bands in the  $\nu(\text{O}-\text{O})$  region. This same product, however, gives a *triplet* of bands when a *scrambled* mixture of  $^{16}\text{O}_2$ ,  $^{16}\text{O}^{18}\text{O}$ , and  $^{18}\text{O}_2$  are used.  $\text{FAIO}_4$  gives a triplet with unscrambled  $^{16}\text{O}_2$  and  $^{18}\text{O}_2$  – showing the

presence of two  $\text{O}_2$  molecules. Once again Density functional theory (DFT) calculation back up the experimental studies (Figure 15).

In this area of chemistry, the use of *laser ablation* to generate metal atoms that may be cocondensed with a wide range of reagents has been particularly useful. Laser ablation often allows monomeric species to be produced when traditional thermal methods for generating metal vapors lead to dimers or oligomers. In this way, the aluminium carbonyls  $\text{Al}(\text{CO})_2$  and  $\text{Al}_2(\text{CO})_2$  – a cyclic molecule that shows some degree of aromaticity – have been prepared.<sup>23</sup> Recent developments in refrigeration techniques have allowed matrix temperatures of 3.5 K to be attained, which, in turn, has allowed pure hydrogen matrices to be deposited. The combination of utilizing laser ablation to generate metal atoms and depositing pure hydrogen as the matrix material has led to the development of new areas of metal hydride chemistry. When laser-ablated aluminium atoms are cocondensed with  $\text{H}_2$  at 3.5 K and the mixture is subjected to ultraviolet irradiation and annealing to 6.5 K the product is the elusive molecule  $\text{Al}_2\text{H}_6$ .<sup>24</sup> Under normal conditions the only known aluminium hydride is the polymer  $(\text{AlH}_3)_n$ . A combination of IR spectroscopy and quantum chemical calculations show that this molecule is isostructural with diborane,  $\text{B}_2\text{H}_6$ . This study may be contrasted with a study of gallium hydrides utilizing more traditional methods of evaporation of gallium vapor from a resistively heated cell and cocondensation of the vapor with ca. 1%  $\text{H}_2$ -doped Ar.<sup>25</sup> In this case, the cyclic molecule  $\text{Ga}(\mu\text{-H})_2\text{Ga}$  is formed.

Laser-ablated aluminium, gallium, indium, or thallium atoms all react with HCN in excess argon.<sup>26</sup> Here both cyanide and isocyanide products viz MCN and MNC are seen ( $\text{M} = \text{Al}, \text{Ga}, \text{In}$  or  $\text{Tl}$ ). No H-containing products are seen. These findings contrast with the results of experiments where laser-ablated group 2 atoms are cocondensed with HCN-doped argon.<sup>27</sup> Beryllium atoms give rise to  $\text{HBeCN}$  and  $\text{HBeNC}$  alongside  $\text{BeCN}$  and  $\text{BeNC}$ . Magnesium, calcium, strontium, and barium yield neither any H-containing products nor any cyanides. Only the isocyanides MNC ( $\text{M} = \text{Mg}, \text{Ca}, \text{Sr}$  or  $\text{Ba}$ ) are formed. Why should the group 2 and 13 atoms behave so differently here? It appears that two mechanisms operate, namely insertion into the C–H bond or attack at the N atom. Calculations suggest that only Be and Al will insert into the C–H bond. With beryllium the H-containing product is seen, but rearrangement to the isocyanide also occurs. For

aluminium direct insertion into C–H gives  $\text{AlCN}$  by loss of an H atom. All of the heavier atoms react by attack at the N atom to yield the isocyanides MNC. When M is a group 2 atom this product is stable, but when M is a group 13 atom the isocyanide rearranges to the more stable cyanide.

### 6.3 Group 14

Isoelectronic with monovalent group 13 molecules are divalent molecules of group 14 elements (*see Germanium: Inorganic Chemistry; Silicon: Inorganic Chemistry and Silicon: Organosilicon Chemistry*). The most populous class of these species are the silylenes, divalent compounds of silicon. It is not appropriate here to provide a detailed review of silicon chemistry since such material is more expertly and comprehensively covered elsewhere. However, it is pertinent to this discussion to make some mention of silylene chemistry.<sup>28</sup>

Silylenes are often generated by pyrolysis. Indeed, the simplest silylene of all,  $\text{SiH}_2$ , may be formed by pyrolysis of  $\text{SiH}_4$ . The presence of  $\text{SiH}_2$  as an intermediate in this reaction, which yields ultimately  $\text{Si}_2\text{H}_6$  and  $\text{H}_2$ , was first suggested over 30 years ago by Purnell and Walsh as a result of their kinetic studies:

the disilane  $\text{Si}_2\text{H}_6$  being formed by an insertion reaction into the Si–H bond of  $\text{SiH}_4$ . As for isoelectronic group 13 molecules such as  $\text{BCl}$  and  $\text{AlCl}$ , it is not surprising to find that silylenes are prone towards insertion.

Silylene,  $\text{SiH}_2$ , was originally studied by electronic spectroscopy in the gas phase. Dubois *et al.*,<sup>29</sup> obtained its spectrum in 1968 and from it were able to estimate values for the bending vibrations of the second electronically excited ( $^1\text{A}_1$ ) and ground ( $^1\text{B}_1$ ) states of  $\sim 860$  and  $\sim 1004 \text{ cm}^{-1}$ , respectively. A rotational analysis of the fine structure of these bands afforded bond angles of  $92^\circ$  and  $123^\circ$  and  $r(\text{Si–H})$  bond lengths of 1.516 and 1.487 Å for the  $^1\text{A}_1$  and  $^1\text{B}_1$  states of silylene. IR detection of silylene awaited the formation of the molecule in a low-temperature matrix. Good yields of this species were obtained by Fredin *et al.*, who cocondensed Si atoms with  $\text{H}_2$ . A spontaneous insertion reaction then yields  $\text{SiH}_2$ :

They obtained a value of  $994.8 \text{ cm}^{-1}$  for the wavenumber of the bending mode, in reasonable agreement with the gas-phase value.

Dimethylsilylene,  $\text{Me}_2\text{Si}$ , long postulated as a reaction intermediate, was first observed directly in 1979; it was formed photochemically. It is now known to be generated also in high-temperature vapors, for example, pyrolysis of

1-methylsilacyclobutane (**43**) in a tenfold excess of butadiene at 1000 K yields 1,1-dimethylsilacyclopent-3-ene (**44**) as a major product (equation 36).

The favored reaction mechanism is that which yields methylsilene and ethylene upon pyrolysis (equation 37).

and the methylsilene rapidly isomerizes to dimethylsilylene (equation 38), which then adds to butadiene to yield the product (**44**).

The isomerization of methylsilene and dimethylsilylene is now a well-known reaction in low-temperature matrices. It is a photochromic process that may be reversed upon irradiation of the matrix at selected wavelengths. Warming to temperatures as low as 100 K promotes the formation of the more thermally stable silylene (equation 39).

Thermochemical calculations show that the principal vapor species in the silicon/oxygen system is the monoxide SiO. This is the most stable molecule to contain a Si–O multiple bond. In 1969, Anderson and Ogden reported the results of matrix-isolation experiments in which the vapor over heated silica, SiO<sub>2</sub>, (at 2000 K) or overheated silica/silicon mixtures (at 1600 K) was cocondensed with excess Ar or N<sub>2</sub>. These results show that alongside the monomer, SiO, the dimer Si<sub>2</sub>O<sub>2</sub> (**45**) and trimer Si<sub>3</sub>O<sub>3</sub> (**46**) are also trapped in the matrix.

A point to be resolved is the extent to which the abundances of the matrix-isolated species reflect the composition of the

high-temperature vapor. Mass spectrometric studies indicate that Si<sub>2</sub>O<sub>2</sub> but not Si<sub>3</sub>O<sub>3</sub> is present in the vapor. Thus it is presumed that Si<sub>3</sub>O<sub>3</sub> is formed during the freezing of the matrix. A reinvestigation of this system has shown that if the temperature of the heated SiO<sub>2</sub> is raised above 1500 K, then the monomer is the most abundant gaseous species; at relatively high concentration, however, dimerization proceeds readily within the matrix. Normal coordinate analysis of the observed frequencies of the IR absorptions and ab initio self consistent field (SCF) calculations have been carried out for Si<sub>2</sub>O<sub>2</sub> and are consistent with the cyclic planar structure (**45**).

Several reactions of matrix-isolated SiO are known. Irradiation of an argon matrix containing SiO and Cl<sub>2</sub> leads, via an insertion reaction, to the product OSiCl<sub>2</sub>, the silicon analog of phosgene:

The IR spectrum of this molecule shows it to be planar with a force constant indicating an Si=O double bond, which is, however, somewhat weaker than the corresponding C=O double bond in phosgene itself.

Molecular SiO<sub>2</sub> is prepared by reacting matrix-isolated SiO with O atoms. Thus codeposition of SiO molecules with microwave-excited O<sub>2</sub> and excess argon yields a species that shows a prominent IR band at 1416.5 cm<sup>-1</sup>.<sup>30</sup> Isotopic substitution experiments allow this feature to be assigned to the asymmetric stretch of a linear SiO<sub>2</sub> molecule. Force constant calculations show that the Si=O bonds of SiO<sub>2</sub> are rather weaker than the C=O bonds of CO<sub>2</sub>. Similarly, matrix-isolated Si<sub>2</sub>O<sub>2</sub> will react with O<sub>2</sub> to yield (**47**), the dimer of SiO<sub>2</sub>, whose structure has been determined by isotopic substitution with <sup>18</sup>O, and the natural abundance of <sup>28</sup>Si, <sup>29</sup>Si, and <sup>30</sup>Si isotopes.

Silicon monosulfide, SiS, is formed if CS<sub>2</sub> gas is passed over silicon heated to 1270 K. Its matrix chemistry shows a strong resemblance to that of SiO. Thus, it reacts with Cl<sub>2</sub> to yield SSiCl<sub>2</sub> and with O atoms to form OSiS, the silicon analog of carbonyl sulfide. The latter molecule is of interest since it is shown to contain both Si=O and Si=S double bonds, while both experimental observations and ab initio calculations confirm the double bond nature of the Si=S linkage in SSiCl<sub>2</sub>.

In 1992, Andrews and his coworkers<sup>31</sup> attempted to characterize small high-temperature molecules in the germanium/oxygen/sulfur system. In this system, only the monoxide, GeO, and the monosulfide, GeS, are well-known, both having been studied in the gas phase by a variety of methods including electronic absorption and emission,

microwave absorption, and IR emission spectroscopy. They have also been observed in low-temperature matrices, while  $\text{GeO}_2$  has been detected only in matrices. Andrews' approach has been to pass vapor-phase reagents through a microwave discharge. The systems studied are: (i) germane + sulfur; (ii) germanium + sulfur; (iii) germanium + oxygen + sulfur. The species present in each system are characterized by their behavior upon annealing the matrix and by isotopic substitution experiments. Thus, the new molecules  $\text{SGeS}$  and  $\text{SGeO}$  are seen. Like  $\text{GeO}_2$ , these are both linear; force constant calculations indicate some multiple bonding between Ge and S atoms although, as expected, such bonding is weak. Another molecule to show  $\text{Ge}=\text{S}$  multiple bonding is  $\text{Me}_2\text{Ge}=\text{S}$ . Michl *et al.* reported the first matrix-isolation study of this molecule, formed either by pyrolysis of the trimer  $(\text{Me}_2\text{GeS})_3$  or by the interaction of S atoms with dimethylgermylene ( $\text{Me}_2\text{Ge}$ ). The vibration of most significance is the  $\text{Ge}=\text{S}$  stretch, which occurs at  $604.5\text{ cm}^{-1}$ . It is attributable to a highly polar true double bond, since single bond Ge–S stretching vibrations typically occur around  $410\text{ cm}^{-1}$ .

As in group 13 chemistry, laser ablation of metal sources has recently been used to allow new areas of group 14 chemistry to be explored. Again the use of dihydrogen matrices gives a route to group 14 metal hydrides. When laser-ablated silicon atoms are cocondensed with  $\text{H}_2$ -doped neon or argon a wide range of hydrides are formed, namely the monomeric species  $\text{SiH}_{1,2,3,4}$  and the dimers  $\text{Si}_2\text{H}_{2,4,6}$ .<sup>32</sup> In pure deuterium matrices the major product is  $\text{SiD}_4$  with smaller amounts of  $\text{SiD}_3$ ,  $\text{Si}_2\text{D}_6$  and  $\text{Si}_2\text{D}_4$ , but no  $\text{SiD}$  or  $\text{SiD}_2$  was seen. Laser-ablated germanium atoms give, in  $\text{H}_2$ -doped neon or argon matrices, all four monomeric hydrides ( $\text{GeH}_{1,2,3,4}$ ). Likewise all four monomeric germanium deuterides are seen in solid pure  $\text{D}_2$ . This suggests that the activation barrier for further reactions of  $\text{GeD}$  and  $\text{GeD}_2$  might be higher than for the corresponding reactions of  $\text{SiD}$  and  $\text{SiD}_2$ .<sup>33</sup> Laser-ablated silicon and germanium atoms also react with ammonia to form 1:1 complexes that exhibit an interesting photochemistry.<sup>34</sup> Upon irradiation at  $\lambda = 290\text{ nm}$ , the insertion product  $\text{HSiNH}_2$  is formed, while photolysis in the region  $250\text{--}280\text{ nm}$  destroys  $\text{HSiNH}_2$  and produces  $\text{SiNH}_2$ . Experiments utilizing thermally generated silicon atoms from a graphite cell heated to  $1450\text{--}1650^\circ\text{C}$  have also been performed.<sup>35</sup> When Si atoms, formed in this way, are cocondensed with  $\text{Me}_2\text{O}$  or  $\text{MeOH}$  and the mixture is photolyzed a wide range of products are formed. These include the silylene  $\text{MeOSiMe}$  and the silanones  $\text{Me}_2\text{Si}=\text{O}$  and  $\text{Me}(\text{H})\text{Si}=\text{O}$ . The direct observation of silanones in detectable quantities under these conditions suggests that such reactions may be useful as a new route for the generation of these transient species.

#### 6.4 Group 15

Small phosphorus (*see Phosphorus: Inorganic Chemistry and Phosphorus–Nitrogen Compounds*) molecules with unusual valencies and coordination numbers are found in

high-temperature vapors. An example is the phosphaeethylene  $\text{CH}_2=\text{PCl}$ . This species has been prepared by pyrolysis of methyl dichlorophosphite (equation 41)

and has been studied in the gas phase by microwave spectroscopy. It is thus shown to have a  $\text{C}=\text{P}$  distance close to  $165.5\text{ pm}$ , a  $\text{P}=\text{Cl}$  distance close to  $206.0\text{ pm}$ , and a  $\text{C}=\text{P}=\text{Cl}$  bond angle of  $103.3^\circ$  (48).

Isoelectronic with  $\text{CH}_2=\text{PCl}$  is  $\text{OPCl}$ . This molecule has been prepared by two separate routes:

It has been studied by IR spectroscopy (when trapped in a low-temperature matrix) and by mass spectrometric studies on the vapor. Isotopic studies ( $^{35}\text{Cl}/^{37}\text{Cl}$  and  $^{16}\text{O}/^{18}\text{O}$ ) allow the  $\text{O}=\text{P}=\text{Cl}$  bond angle to be calculated from the IR spectra at ca.  $105^\circ$  (i.e. close to the bond angle of  $\text{CH}_2\text{PCl}$ ). From the observed appearance potential ( $20.9\text{ eV}$ ) of  $\text{P}^+$  [ $\text{AP}(\text{P}^+)$ ] in the mass spectrum of  $\text{OPCl}$ , it is possible to estimate the enthalpy of atomization of  $\text{OPCl}(\text{g})$  via the Born–Haber cycle (Scheme 6). Hence, since the standard enthalpies of formation of  $\text{P}(\text{g})$ ,  $\text{O}(\text{g})$ , and  $\text{Cl}(\text{g})$  are all known, the standard enthalpy of formation of  $\text{OPCl}(\text{g})$  [ $\Delta H_{f298}^\circ(\text{OPCl})$ ] may be estimated as  $-250.7\text{ kJ mol}^{-1}$ .

A reaction similar to that with  $\text{OPCl}_3$  occurs between  $\text{OPFX}_2$  vapor ( $\text{X} = \text{Cl}$  or  $\text{Br}$ ) and silver to produce  $\text{OPF}$ , a molecule that is isoelectronic with  $\text{SiF}_2$  and  $\text{SO}_2$ . IR studies of Ar matrices and mass spectrometric studies of the vapor indicate that the  $\text{O}=\text{P}=\text{F}$  bond angle =  $109 \pm 5^\circ$  and  $\Delta H_{f298}^\circ(\text{OPF}(\text{g})) = -404.4\text{ kJ mol}^{-1}$ .

Even more uncommon than molecules containing trivalent two-coordinate phosphorus are those that contain pentavalent

Scheme 6

three-coordinate phosphorus. The molecule  $\text{O}_2\text{PCl}$  may be prepared cleanly by UV irradiation of an Ar matrix containing  $\text{OPCl}$  and  $\text{O}_3$ :

The formation of  $\text{O}_2\text{PCl}$  from  $\text{OPCl}$  is illustrated by the spectra shown in Figure 16. IR spectra show  $\text{O}_2\text{PCl}$  to be a planar molecule (49) with a relatively wide O–P–O bond angle ( $\sim 135^\circ$ ) and an unusually strong P–Cl bond (with a stretching force constant of  $370 \text{ N m}^{-1}$ ). These observations may be rationalized by ab initio calculations.

**Figure 16** (a) IR spectrum of  $\text{OPCl}$  (derived from the reaction of  $\text{OPCl}_3$  with Ag) cocondensed with  $^{18}\text{O}_3$  in an argon matrix at ca. 15 K; (b) IR spectrum of the sample following UV irradiation for 15 min, showing the formation of the photoproduct  $\text{O}_2\text{PCl}$ . (Reprinted with permission from Ahlrichs *et al.*, *J. Am. Chem. Soc.*, 1986, 108, 3596. © 1986 American Chemical Society)

Several analogs of  $\text{OPCl}$ , produced in high-temperature vapors, have likewise been the subjects of matrix-isolation experiments. For example,  $\text{SPCl}$  can be made by the high-temperature reaction of  $\text{SPCl}_3$  with Ag. It has an  $\text{SPCl}$  bond angle of about  $110^\circ$ . Preparation of  $\text{OAsCl}$  presents a more difficult challenge since the obvious precursor,  $\text{OAsCl}_3$ , does not survive long, even at normal temperatures. However,  $\text{OAsCl}$  can be generated if a gaseous  $\text{AsCl}_3/\text{O}_2$  mixture is passed over silver heated to about 1350 K. Less successful have been attempts to study  $\text{OSbCl}$ . Although a reaction occurs between  $\text{SbCl}_3$ ,  $\text{O}_2$ , and Ag at about 1350 K,  $\text{Sb}_4\text{O}_6$  is a ubiquitous product alongside  $\text{OSbCl}$ , and IR absorptions of the binary oxide mask those of the ternary species.

The phosphorus nitride radical  $\text{PN}$ , isoelectronic with  $\text{SiO}$ , has recently been detected in interstellar space. It is readily prepared in high-temperature vapors either by heating solid  $\text{P}_3\text{N}_5$  to 1100 K or by dehalogenation of cyclic  $(\text{NPCl}_2)_3$  with Ag:

When the vapor containing  $\text{PN}$  is cocondensed with excess krypton at 10 K the  $\text{PN}$  monomer and  $\text{P}_3\text{N}_3$  trimer are seen, but there is no hint of the dimer  $\text{P}_2\text{N}_2$ . The monomer is readily converted into the trimer, as illustrated by the spectra shown in Figure 17, if the matrix is annealed to 35 K. Isotopic substitution with  $^{15}\text{N}$  and ab initio SCF calculations show that  $\text{P}_3\text{N}_3$  has a planar cyclic structure (50).

The formation of  $\text{P}_3\text{N}_3$  from  $\text{P}_2$  and  $\text{N}_2$  molecules is shown to be an endothermic process, while the formation of  $\text{P}_3\text{N}_3$  from three molecules of  $\text{PN}$  is found to be strongly favored.  $\text{PN}$  reacts with silver atoms in hydrocarbon glasses at 77 K. The product, as determined by ESR spectroscopy, is  $\text{AgPN}$ . Local density functional calculations suggest that Ag bonds exclusively to the P nucleus of  $\text{PN}$  in a bent geometry with an Ag–P–N bond angle close to  $97.4^\circ$ . An interaction is also found between copper(I) chloride and  $\text{PN}$  molecules in solid argon. Here the interaction appears to be between the Cu and N atoms and the product is a linear species  $\text{ClCuNP}$ .<sup>36</sup>

Various routes have been used to generate matrix-isolated phosphorus oxide radicals, for example,  $\text{PO}_2$  and  $\text{PO}_3$ . These are: (i) codeposition of phosphine with O atoms from a microwave discharge source; (ii) the matrix reaction of  $\text{P}_2$  (generated by heating GaP) and  $\text{O}_3$ ; (iii) laser ablation of  $\text{P}_4\text{O}_{10}$ ; (iv) laser ablation of red P in a stream of  $\text{O}_2$ . Both

**Figure 17** IR spectra of the  $^{14}\text{N}/^{15}\text{N}$  isotopomers of PN and  $\text{P}_3\text{N}_3$  (formed from PN upon annealing the matrix to 25–35 K) in a krypton matrix. (Reprinted from Ref. 36a © 1977, with permission from Elsevier)

$\text{PO}_2$  and  $\text{PO}_3$  are seen in all four systems; these are highly reactive species so it is not surprising to see  $\text{P}_2\text{O}_5$  also, formed by reaction of  $\text{PO}_2$  with  $\text{PO}_3$  upon diffusion. The reaction of the high-temperature molecule  $\text{P}_2$  with  $\text{O}_3$  yields the new molecule  $\text{P}_2\text{O}$  alongside cyclic  $\text{P}_4\text{O}_2$ , while the reaction of  $\text{PH}_3$  with  $\text{O}$  generates also the H-containing species  $\text{HPO}$ ,  $\text{HOPO}$ ,  $\text{H}_2\text{PO}$ , and  $\text{HPOH}$ . The nature of the products formed by the laser ablation of  $\text{P}_4\text{O}_{10}$  depends upon the nature of the solid material used. The hexagonal form, the commercially available variety, gives mainly molecular  $\text{P}_4\text{O}_{10}$  with some  $\text{P}_2\text{O}_5$  and  $\text{PO}_2$ . By contrast, the polymeric orthorhombic form yields little molecular  $\text{P}_4\text{O}_{10}$  but much higher quantities of  $\text{PO}$ ,  $\text{PO}_2$ ,  $\text{P}_2\text{O}$ , and  $\text{P}_2\text{O}_5$ . A similar distribution of products is obtained if red phosphorus is laser-ablated in a stream of  $\text{O}_2$ .

The phosphorus sulfides  $\text{PS}$ ,  $\text{P}_2\text{S}$ , and  $\text{PS}_2$  have been made by allowing  $\text{P}_4$  and  $\text{S}_8$  vapors to react in an Ar discharge.<sup>37</sup> Isotopic substitution studies show that  $\text{P}_2\text{S}$  is linear like  $\text{P}_2\text{O}$  and  $\text{N}_2\text{O}$ , while  $\text{PS}_2$  is bent like  $\text{PO}_2$  and  $\text{NO}_2$ . The species in the vapor above heated  $\text{P}_4\text{S}_{10}$  have been the focus of some controversy. It has been claimed that  $\text{P}_4\text{S}_{10}$  sublimates undissociated. However, matrix-isolation experiments reveal

that the molecule  $\text{P}_4\text{S}_9$  is also present in the vapor even at temperatures as low as 450 K. Some  $\text{P}_2\text{S}_5$  is also formed upon vaporization of  $\text{P}_4\text{O}_{10}$ . By contrast, volatilization of pure  $\text{P}_4\text{S}_9$  solid at 450 K yields no vapor-phase  $\text{P}_4\text{S}_9$ ; rather,  $\text{P}_4\text{S}_7$  and  $\text{P}_4\text{S}_{10}$  are generated by disproportionation.

The vapor species formed upon heating arsenic(V) oxide in vacuo include the four decomposition products  $\text{As}_4\text{O}_n$  ( $n = 6$  to 9) as well as  $\text{As}_4\text{O}_{10}$  (**51**), which has been characterized by its IR spectrum.

## 6.5 Group 16: Oxides and Oxy Salts

Several routes exist to molecular metal oxides. These include reactions of metal atoms with oxygen or photolysis of a suitable precursor, for example, a metal carbonyl in the presence of  $\text{O}_2$  (see Section 5.3). Both of these methods lend themselves particularly well to trapping and detection by matrix isolation. A third means of generating molecular metal oxides is to heat a solid oxide sample, thus producing molecules in the vapor. The resulting gaseous species can then be studied either directly in the gas phase, or, following freezing with excess inert gas, in a matrix. A wide range of matrix-isolated metal monoxide molecules have been made in this way.

Higher oxides may also be formed. When  $\text{WO}_3$  is heated to 1250–1700 K, the vapor contains a number of species of which the principal one appears to be the trimer  $\text{W}_3\text{O}_9$ . Gas electron diffraction studies suggest that the most likely structure of this species is one containing a six-membered ring (**52**). Mass spectrometry confirms the presence of  $\text{W}_3\text{O}_9$  in the vapor and suggests also that the dimer  $\text{W}_2\text{O}_6$  and tetramer  $\text{W}_4\text{O}_{12}$  are present. In order to make monomeric  $\text{WO}_3$ , a different technique must be employed. This is sputtering of a W electrode in a mixture of  $\text{O}_2$  and an inert gas followed by rapid freezing of the products. IR experiments employing isotopic substitution show that  $\text{WO}_3$  has planar  $D_{3h}$  symmetry (**53**).

Dimanganese heptoxide,  $\text{Mn}_2\text{O}_7$ , is a volatile liquid and readily sublimates undissociated. The heavier congener,  $\text{Re}_2\text{O}_7$ ,

is less volatile and only vaporizes upon heating to about 400 K. It appears to sublime without dissociation, though an unidentified IR band ubiquitously appears in the spectrum of the matrix-isolated compound. This band has been variously attributed to: (i) aggregates of  $\text{Re}_2\text{O}_7$ ; (ii)  $\text{ReO}_3$  formed by loss of  $\text{O}_2$  from  $\text{Re}_2\text{O}_7$  and dissociation upon heating; (iii)  $\text{HReO}_4$  formed by reaction of  $\text{Re}_2\text{O}_7$  with traces of moisture. A definitive solution to this problem is not yet forthcoming, and the situation is complicated by the known rather complex behavior of rhenium oxides at high temperature. Upon volatilization at ca. 750 K,  $\text{ReO}_3$  generates  $\text{Re}_2\text{O}_7$  via the disproportionation reaction

which generates  $\text{Re}_2\text{O}_7$  in the gas phase while leaving a residue of solid, involatile  $\text{ReO}_2$ . What mass spectrometric and matrix-isolation studies have so far failed to confirm is whether or not the  $\text{Re}_2\text{O}_7$  is accompanied by  $\text{ReO}_3$  in the vapor. Again the situation is complicated by the presence of  $\text{HReO}_4$  whenever any traces of water are found.

Many structural studies have been made on the species present in the vapors above oxysalts such as alkali metal nitrates, chlorates, perrhenates, and so on. In part, the interest in such work lies in determining the mode of coordination of the metal atom to the oxyanion in the monomeric vapor species. Both gas electron diffraction and matrix isolation have been employed to seek an answer to this question.

Three plausible structures may be envisaged (54–56) for a simple monomeric metal nitrate such as  $\text{TlNO}_3$ . Electron diffraction studies indicate that the bidentate structure (55) is preferred, a mode of ligation that is also adopted by  $\text{MReO}_4$  and  $\text{MClO}_4$  ( $\text{M} = \text{Li}, \text{K}, \text{Cs}, \text{or Tl}$ ). Such structures may readily be determined by IR spectroscopy involving isotopic substitution with  $^{18}\text{O}$ . In Figure 18 are illustrated IR spectra for  $\text{CsReO}_4$ , 50% enriched in  $^{18}\text{O}$ ,<sup>38</sup> assuming bidentate coordination. Other metal oxysalts showing bidentate coordination are metal phosphates ( $\text{MPO}_3$ ) and phosphites ( $\text{MPO}_2$ ) and their arsenic analogs (57, 58). Metal sulfates and their selenium analogs also tend to show bidentate coordination. Molecular thallium sulfate has been prepared in situ in low-temperature matrices by cocondensing  $\text{Tl}_2\text{O}$  vapor with  $\text{SO}_2$  and excess Ar:

Alkali metal sulfates or selenates are generated in the gas phase by heating the appropriate solid material. Both

**Figure 18** IR spectra of  $\text{CsReO}_4$  in nitrogen matrices: (a)  $\text{CsRe}^{16}\text{O}_4$ ; (b)  $\text{CsReO}_4$  50% enriched in  $^{18}\text{O}$ ; (c) calculated spectrum assuming a bidentate structure. (Ref. 38a. Reproduced by permission of The Royal Society of Chemistry)

adopt a bis-bidentate  $D_{2d}$  structure (59). For the molecular metal selenites,<sup>39</sup> it appears that the selenite anion has an unsymmetrical structure. As shown in Figure 19, the best fit between observed and calculated IR spectra is found for O–Se–O bond angles of 101, 115, and 115°. This finding suggests the possibility of monodentate (60) or a combination of mono- and bidentate (61) coordination of the cation to the central selenite pyramid.

In contrast to the above molecules, cesium chlorate,  $\text{CsClO}_3$ , provides a rare example of tridentate coordination of a metal cation to an oxyanion (62).

**Figure 19** Matrix IR spectra obtained from the vaporization of alkali metal selenites: (a) spectrum obtained from  $\text{Na}_2\text{SeO}_3$ ; (b) spectrum obtained from  $\text{Cs}_2\text{SeO}_3$ ; (c) calculated spectrum assuming all the O–Se–O angles are  $101^\circ$ ; (d) calculated spectrum assuming the three O–Se–O angles are  $101^\circ$ ,  $115^\circ$ , and  $115^\circ$ ; (e) high-resolution spectrum of the  $A''$  band of  $\text{Cs}_2\text{SeO}_3$ ; (f) calculated spectrum as in (d). Devlin has reported some interesting results regarding the solvation of  $\text{LiNO}_3$  molecules in a low-temperature matrix.<sup>40</sup> In a pure Ar matrix,  $\text{LiNO}_3$  adopts structure (55) and the degenerate  $\nu_3$  mode of the trigonal nitrate ion is split into two components separated by  $262 \text{ cm}^{-1}$ . However, if  $\text{LiNO}_3$  is cocondensed with Ar-containing Lewis bases such as water or Tetrahydrofuran (THF) then the Lewis base molecules coordinate to the lithium ion. The splitting of  $\nu_3$  thus decreases in regular steps corresponding to an increase in coordination number of the Li ion. In Figure 20 are illustrated the IR spectra of  $\text{LiNO}_3$  in Ar matrices doped with concentrations of THF ranging from 1 to 25%. One remarkable feature of these experiments is that the coordination number of the Li ion reaches a higher value in the matrix than it does in solution!

## 6.6 Group 17: Halides

Simple alkali metal halide molecules, for example  $\text{NaCl}$  and  $\text{KCl}$ , are found in the vapors above heated samples of the solid compounds. These vapor species have been studied by IR spectroscopy of gases and matrices, and by gas electron diffraction. The studies show that planar rhombic dimers are also present.

**Figure 20** IR spectra of  $\text{LiNO}_3$  in (a) 1% THF-doped solid argon; (b) 7% THF-doped solid argon; (c) 25% THF-doped solid argon; (d) pure solid THF (all at 25 K); (e) pure THF solution at 298 K. The numbers refer to  $n$  in  $\text{LiNO}_3 \cdot (\text{THF})_n$ . (Reproduced by permission of American Institute of Physics from Ritzhaupt *et al.*, *J. Chem. Phys.*, 1985, **82**, 1167)

There has, over the years, been some controversy regarding the structure adopted by the dihalide molecules  $\text{MCl}_2$  ( $\text{M} = \text{Ca}, \text{Cr}, \text{Mn}, \text{Fe}, \text{Co}, \text{Ni}, \text{and Zn}$ ). One school of thought has it that these molecules are linear, a view supported by the results of gas electron diffraction, and molecular beam deflection studies. In  $\text{N}_2$  matrices, however,  $\text{CoCl}_2$  and  $\text{NiCl}_2$  are strongly bent, probably owing to interactions with the  $\text{N}_2$  host, and even in Ar matrices there is evidence that  $\text{FeCl}_2$ ,  $\text{CoCl}_2$ , and  $\text{NiCl}_2$  are all slightly bent with bond angles around  $160^\circ$ . Those who follow the results of matrix-isolation spectroscopy will be reminded of the controversy that once attended the structure of molecular  $\text{AlCl}_3$ . Gas electron diffraction supported the expected planar geometry. Matrix-isolation studies were in conflict, one group preferring a pyramidal shape while another, that of Beattie and Ogden, a

**Figure 21** IR spectra of  $\text{CsUF}_6$ : (a) in an argon matrix; (b) in a nitrogen matrix (both at 14 K). (Reproduced by permission of The Royal Society of Chemistry from Arthers *et al.*, *J. Chem. Soc., Dalton Trans.*, 1984, 711)

planar molecule. The discrepancy was finally resolved when it was realized that the nonplanarity of  $\text{AlCl}_3$  in some matrices results from weak complex formation.

It is clear that interactions between guest molecules and the matrix host can, in certain instances, cause significant structural perturbations to the guest species. An exemplary case is provided by  $\text{CsUF}_6$ . The spectra of this molecule (Figure 21) look quite different in argon or nitrogen matrices. This difference appears to result from a change in coordination of the  $\text{Cs}^+$  cation to the  $\text{UF}_6^-$  anion upon moving from one matrix to the other. In argon the interaction is tridentate (**63**), in nitrogen it is bidentate (**64**). Thus, the overall molecular symmetry is lowered from  $C_{3v}$  to  $C_{2v}$  upon moving from argon to nitrogen matrices.

It is appropriate to end with the caveat that it is a weakness shared by many of these studies of high-temperature salt molecules that the IR characterization of the species does not extend to motions of the cation. Hence the location of the cation, or cations, has to be inferred circumstantially from the perturbation experienced by the anion. The basis of the argument does make the results vulnerable to misinterpretation, and there is no doubt that the surest results relate to molecules whose identities can be vouched for independently, for example by gas electron diffraction studies.

## 6.7 Group 18

One of the most interesting developments in the study of main group chemistry by matrix-isolation spectroscopy over the past few years has been the great expansion of the chemistry of the rare gases. Although the following work does not involve generation of reactive species in high-temperature vapors, it is included here because of its importance in the current understanding of rare gas chemistry. Much of this work has been done in the laboratories of Räsänen and his coworkers at Helsinki, Finland. In 1995 it was shown that irradiation of HI in a xenon matrix led to the formation of the species  $\text{HXeI}$ . This had charge transfer characteristics  $[(\text{HXe})^+\text{I}^-]$  and was identified by its strong H–Xe stretching vibration.<sup>41</sup> The list of such molecules has grown over the years and now includes krypton and argon species, for example,  $\text{HKrCl}$  and  $\text{HArF}$  and those with a wide range of electronegative components, for example,  $\text{HXeOH}$ ,  $\text{HXeSH}$ ,  $\text{HXeH}$ ,  $\text{HXeCN}$ ,  $\text{HxeNC}$ , and  $\text{HXeNCO}$ . It has been shown that these neutral rare gas compounds form from the neutral fragments  $\text{H} + \text{Y} + \text{Rg}$  where H and Y fragments are produced by photolysis of the HY precursor and Rg is the rare gas. The intrinsic stability of the molecules is of great interest and it has been shown, for example, that  $\text{HXeBr}$  and  $\text{HXeCl}$  are stable in neon matrices, indicating intrinsic stability rather than a stability that depends upon the presence of a Xe (or Kr) matrix host. These molecules will form weak, but stable complexes in matrices. Thus  $\text{HXeOH}$  gives the complexes  $\text{HXeOH}\cdot\text{H}_2\text{O}$  and  $\text{HXeOH}\cdot(\text{H}_2\text{O})_2$  in  $\text{H}_2\text{O}$ -doped argon matrices while  $\text{HArF}$ ,  $\text{HKrF}$  and  $\text{HKrCl}$  all form  $\text{N}_2$  complexes in  $\text{N}_2$ -doped matrices. The yields of  $\text{HRgY}$  molecules are increased by annealing the matrix as the mobility of the H atoms formed by photodissociation of HY is increased. In this way the kinetics of the formation of  $\text{HKrCl}$  and  $\text{DKrCl}$  by annealing of krypton matrices containing H (or D) and Cl atoms (formed themselves by photodissociation of  $\text{HCl}$  or  $\text{DCl}$ ) may be used as a measure of the mobility of H and D atoms in low-temperature matrices. Not surprisingly the D atoms are shown to migrate at a slower rate than H atoms under these conditions.

It must be remembered that there is an enormous amount of current research involving the chemistry of reactive intermediates. In this short review, it has been possible only to describe selected areas of work. It is hoped, however,

that this will illustrate the principles of how such research is carried out and how the results of these studies have importance for a wide range of chemical and other scientific applications. The interdisciplinary nature of this research should also be noted. Work by spectroscopists – using a range of techniques – synthetic chemists, theoreticians, and kineticists is all brought together. The most successful findings in this area usually require input from those with a range of specialized interests.

## Abbreviations

cod = 1,5-cyclooctadiene; MNDO = modified neglect of diatomic overlap; NMI = *N*-methylimidazole; PPN<sup>+</sup> = [(Ph<sub>3</sub>P)<sub>2</sub>N]<sup>+</sup>; pyO = pyridine-*N*-oxide.

## 1 INTRODUCTION

Silicon is the most abundant (≈27.7%) electropositive element in the Earth's crust and second only to oxygen in overall abundance, the two elements together accounting for approximately four out of every five atoms on the surface of the Earth. Elemental silicon does not seem to occur naturally but it is usually combined with oxygen to form the very wide variety of silicates (*see Silica and Zeolites*) that make up many of the world's rocks. Silicon is not found to any appreciable extent in the atmosphere, and only relatively small amounts are found in the hydrosphere, although organisms such as diatoms and some plants are able to extract silicon in the form of silica or silicic acid from aqueous solutions and use solid deposits of silica as skeletal or protective material. For example, hydrated silica, SiO<sub>2</sub>·*n*H<sub>2</sub>O, is used by a number of organisms for protection and strength, for example, in plant leaves and the teeth of limpets. For general reviews on silicon in biology, see References 1–3 and Section 1.2 below.

Despite the ubiquitous nature of silicate materials and humankind's historical use of them, elemental silicon was not isolated until the nineteenth century when Berzelius used

potassium to reduce potassium hexafluorosilicate (equation 1). (For a review of the history of the discovery of the element and its occurrence, see Gmelin.<sup>4</sup>)

The mid-nineteenth century also saw the preparation of simple, volatile, covalent compounds such as (EtO)<sub>4</sub>Si, SiCl<sub>4</sub>, and SiH<sub>4</sub> and the first organometallic silicon compound (Et<sub>4</sub>Si) by Friedel and Crafts in 1863. Considerable growth in non-silicate silicon chemistry occurred in the first part of the twentieth century with Stock and Kipping working on silanes (Si–H containing compounds) and organosilicon compounds, respectively. This work then set the foundation for the enormous growth that silicon chemistry has seen since the 1940s, particularly in the fields of polymers containing silicon in their backbone, and organosilicon compounds that have been studied to see how their chemistry compares with that of carbon compounds. This article will deal only with the inorganic compounds of silicon and excludes all compounds containing a silicon to carbon bond (such organosilicon compounds may be found in the article *Silicon: Organosilicon Chemistry*) except for silicon carbide and simple silyl cyanides in which the carbon may be viewed as 'inorganic'. Compounds that cannot be isolated under normal conditions and which are fleeting intermediates will be mentioned briefly but not discussed in detail. As in other areas of chemistry, computational work on silicon compounds has grown rapidly in recent years; an excellent comparative review of the theoretical aspects of Si, Ge, Sn, and Pb compounds can be found in Reference 5.

### 1.1 Elemental Silicon and its Production

The production of high purity silicon has become increasingly important during the last three decades as its semiconductor properties have been utilized in an enormous variety of electronic devices.<sup>6</sup> The early work on the chemical and physical properties of silicon and its simple inorganic compounds has been discussed in detail.<sup>7</sup> Large-scale production of silicon is achieved by reduction of quartz, SiO<sub>2</sub>, with carbon at approximately 1700 °C (equation 2), that is, well above the melting point of silicon.

The silicon prepared by this route is known as metallurgical grade or ferrosilicon and contains varying amounts of iron which is derived from impurities in the silica used and by addition of iron to the reduction process. Leaching impurities from the ferrosilicon affords higher purity silicon (ca. 98.5%), containing Fe, Al, Ca, and O as main impurities, which can be used for chemical purposes such as the direct synthesis of organochlorosilanes (*see Silicon: Organosilicon Chemistry*).

The preparation of high purity silicon for use in the electronics industry has been achieved using several methods relying on the formation, purification by distillation, and reduction of volatile silicon compounds such as  $\text{SiF}_4$ ,  $\text{SiHCl}_3$ , and  $\text{SiH}_4$  (for preparations of these compounds, see below). Scheme 1 outlines the basic features of the process to prepare single-crystal silicon using  $\text{HSiCl}_3$  as the volatile silane, the low boiling point of which enables distillation to give a much higher purity starting material than in the  $\text{SiO}_2$  reduction where physical separation of impurities is difficult.<sup>6</sup>

A second method of Si preparation involves the thermal decomposition of  $\text{Na}_2\text{SiF}_6$  to give  $\text{SiF}_4$ , which is then reduced by sodium to give a mixture of  $\text{NaF}$  and  $\text{Si}$ . The sodium salts are then removed by aqueous acid leaching to give a high quality powder of  $\text{Si}$ .<sup>8</sup> A more recent and widely used method involves the thermal decomposition of  $\text{SiH}_4$  (which can be obtained in higher purity than  $\text{SiHCl}_3$  from redistribution reactions, Scheme 2) to give high purity polycrystalline rods.<sup>9</sup>

The high purity silicon prepared by the methods above is either polycrystalline or in the form of a microcrystalline powder. Two methods are used to prepare

**Scheme 1**

**Scheme 2**

large, dislocation-free single-crystal silicon: the Czochralski method and the zone-refining or float zone method. The equipment used in the Czochralski method is shown in Figure 1. The graphite crucible is filled with polycrystalline pieces which are then melted. A seed crystal is dipped into the melt and then slowly withdrawn such that the silicon slowly crystallizes as it is removed from the hot zone. Both the graphite crucible and the pulling seed are rotated, often counter to each other, so that resistivity and oxygen content can be made uniform. Single crystals of 30-cm diameter and more than 1 m in length can be prepared in this way, but it is difficult to keep the large volume of molten silicon free from contamination by the silica container and from impurities in the inert gas blanket for the long periods of time required.<sup>6</sup>

The zone-refining method is shown in Figure 2. In this method, only a small band of the polycrystalline silicon rod is melted at any one time and the molten zone is moved along the length of the rod, and impurities dissolve preferentially in the molten phase and so are drawn to the end of the rod. Again, single-crystal silicon crystallizes on a seed crystal, and single-crystal growth continues as the melt zone is moved. This method also allows large single crystals to be prepared. Contamination is more easily controlled as only a small fraction of the silicon is molten at any one time and the liquid zone is not in contact with any solid container. The float zone method can be applied more than once to a silicon rod to increase purity. Table 1 gives a summary of some of the more important data associated with elemental silicon and the silicon atom.

The chemistry that can be carried out at a silicon surface has become more significant in recent years as the dimensions

of electronic devices based on crystalline silicon have become ever smaller. In addition to older methods such as doping, etching, and deposition of films to modify Si surfaces, newer studies have shown that reactions involving, for example,

unsaturated species such as dienes, alkynes, and aromatic compounds can also occur and lead to Si–C bond formation. (These studies have been reviewed; see References 11 and 12). The reaction of elemental silicon, usually alloyed with copper, is the basis of the ‘Direct Process’ used for the preparation of simple alkylchlorosilanes (for a review see Reference 13).

The etching of silicon in the form, for example, of a wafer can be achieved in many ways and leads to a material known as ‘porous silicon’. Etching can be achieved chemically, photochemically, or electrochemically using electrolytes usually comprising solutions of concentrated aqueous HF containing various additives. The size of the pores produced in the silicon can be varied from about  $1 \times 10^{-9}$  to  $1 \times 10^{-5}$  m, depending on the conditions used. The nature of the pores can also be varied greatly to include, for example, pores that are spongelike or cylindrical. The interest in porous silicon arises from its light-emitting properties such as photoluminescence and chemiluminescence and from its physical properties such as its high surface area (hundreds of square meters per cubic centimeter). If HF etching is used to prepare the porous silicon then the surface of the silicon is terminated by Si–H bonds and these can be used to carry out further chemistry at the surface such as oxidation to give Si–OH groups or hydrosilylation to give pendent organic groups. Such surface modification means that the materials may be used for bio- and chemical-sensing, new materials supports, and for mass spectrometry applications. The many methods of preparation and the potential uses of porous silicon have been reviewed.<sup>14–17</sup>

## 1.2 Silicon in Biology

Silica dissolves from the mineral environment into water to become bioavailable as silicic acid, Si(OH)<sub>4</sub>, and can reach a concentration of up to 2 mM at near neutral pH. At higher concentrations, oligomerization takes place followed by the formation of colloidal particles of hydrated silica, SiO<sub>2</sub>·xH<sub>2</sub>O. Silicic acid in water is used by organisms such as diatoms and radiolaria to build up complicated exoskeletons of hydrated silica and plants can take in silicic acid to build up silica materials that can strengthen stems and leaves or make protective spikes (see **Biom mineralization**). Thus, terrestrial plants can, at an average composition of 0.15% Si, contain more silicon than magnesium or phosphorus. Clearly, animals eating vegetation may consume large amounts of silicon in their normal diet. The effects of silicon in diet and silicon deficiency have been the subjects of several studies that have been reviewed.<sup>18</sup> It seems that although the silicon in higher animals plays neither a significant structural role nor participates in Si–C bond formation, it is useful in its interaction with toxic metals such as aluminum where it can affect the metal’s bioavailability, distribution, and excretion. The bio-manipulation of silicic acid and its polycondensation into silica has been shown to

involve several classes of proteins that have been named 'frustulins' (isolated from cell walls of diatoms), 'silaffins' (found occluded within biosilica) and 'silicateins' (also found occluded in silica needles). The mechanisms used by these biological controllers of silica production are of significant interest as they may be used to produce synthetic silica with high surface area and/or well-defined porosity.<sup>19</sup> Numerous reviews of the various aspects of biological silicon chemistry in plants, concerning, for example, silicon deposition in higher plants, the effects of silicon on plant growth and crop yield, and silicon resources for agriculture can be found in Reference 20.

## 2 ONE-COORDINATE COMPOUNDS

Compounds containing silicon bonded to only one other atom are unstable and are usually only generated and observed as reactive intermediates of short half-life. Silicon compounds subjected to flash photolysis or electrical discharges in the gas phase produce short-lived species SiX (X = H, F, Cl, Br, I, C, Si, etc.), the band structure of which have been studied in detail.<sup>21</sup> The structures, electronic configurations, and so on of SiX (X = H, F, Cl, Br, I, N, O, etc.) have also been the subject of MNDO (modified neglect of diatomic overlap) and other calculations.<sup>22,23</sup>

Silicon monoxide, SiO, is formed in a wide range of reactions such as those between SiO<sub>2</sub> and Si, SiO<sub>2</sub> and Mg, SiO<sub>2</sub> and CO, and SiCl<sub>4</sub> and O<sub>2</sub>, at high temperatures. The reaction between Si and SiO<sub>2</sub> (equation 3) in an oxygen-free atmosphere may be troublesome in the high-temperature postoxidation annealing process used during the fabrication of semiconductor devices. However, the reaction is inhibited if O<sub>2</sub> is present (which presumably oxidizes SiO back to SiO<sub>2</sub> as it is formed) during the annealing process.<sup>24</sup> When quartz, SiO<sub>2</sub>, is heated to sufficiently high temperatures for vaporization to occur, the predominant species in the gas phase is found to be SiO. Commercially SiO has been produced as a dark brown cokelike mass on a substrate from the reaction of Si with SiO<sub>2</sub> at 1250 to 1400 °C (for a review on the production, properties, and applications of SiO, see Reference 25). As a fine brown powder, freshly prepared SiO is pyrophoric and readily oxidizes to give SiO<sub>2</sub>. Rapid cooling on to a cold surface, or condensation into an inert gas mixture, enables SiO to be isolated and studied spectroscopically. Thus condensation of an Ar/SiO mixture on to a cold copper surface allows IR spectroscopic identification of SiO, (SiO)<sub>2</sub>, and (SiO)<sub>3</sub> with characteristic IR absorbances at 1226, 803 and 768, and 972 cm<sup>-1</sup> respectively. The IR data suggest that (SiO)<sub>2</sub> has a cyclic structure.<sup>26</sup> Monomeric SiO can react in a matrix with metals, for example, reaction with Pd gives PdSiO the bonding in which is thought to be similar to the corresponding carbonyl, PdCO. The reactions of SiO in noble

Scheme 3

gas matrices have been reviewed.<sup>27</sup>

Silicon monosulfide, SiS, is formed in the high-temperature reaction between silicon and sulfur, or between SiO<sub>2</sub> and metal sulfides such as FeS or ZnS. It is also formed on passing H<sub>2</sub>S over Si at 1500 K and it can be trapped in an argon matrix and analyzed by IR spectroscopy, showing a band at 739 cm<sup>-1</sup> for SiS. The monosulfide reacts in the matrix with co-condensed COS to give linear SiS<sub>2</sub>, which absorbs at about 900 cm<sup>-1</sup>.<sup>28</sup>

There is continuing interest in the gas-phase reactions of silicon cations because of the increasing use of chemical vapor deposition in the semiconductor industry and the interest in the preparation of three-coordinate silicon cations in condensed phases. Atomic silicon cations, Si<sup>+</sup>, react with a wide range of inorganic and organic species in the gas phase to give more complicated species that can be investigated by ion cyclotron resonance, flow tube techniques, or ion-trap techniques. Some simple examples of these reactions are shown in Scheme 3. Initially a long-lived intermediate form, it then breaks down to give the silicon-containing cation and H<sup>•</sup>. These and other reactions of Si<sup>+</sup> have been reviewed.<sup>29</sup>

Metal silicides such as NaSi, KSi, and CaSi<sub>2</sub> that appear from their empirical formulas to contain single-coordinate Si are, in fact, complicated three-dimensional solids. Metal silicides have found increasingly numerous applications in the semiconductor industry, in thermoelectric devices, and in structural applications. They may be prepared in numerous ways, for example, by depositing a layer of metal onto Si and then heating, by coevaporation of a metal and Si, or by chemical vapor deposition using a mixture of SiH<sub>4</sub>, H<sub>2</sub>, and a volatile metal complex. Metal silicides exhibit a wide variety of structures including isolated Si<sup>4-</sup> ions such as in Mg<sub>2</sub>Si, tetrahedral Si<sub>4</sub><sup>4-</sup> ions as in KSi, layers as in CaSi<sub>2</sub>, and three-dimensional networks as in SrSi<sub>2</sub>. These are beyond the scope of this review, but have been reviewed elsewhere.<sup>30-33</sup>

## 3 TWO-COORDINATE COMPOUNDS

Two-coordinate X<sub>2</sub>Si: species are called silylenes (by analogy with carbenes) and are best described as reactive intermediates which may be trapped and observed spectroscopically at low temperatures in an inert matrix, but most of which have short lifetimes under normal conditions. The structures and electronic configurations of X<sub>2</sub>Si: (X = H, F,

Cl, Br, O, etc.) have been calculated by MNDO and other more sophisticated theoretical methods.<sup>22,23,34,35</sup> Experimental values for the X–Si–X angle in  $X_2Si:$  species have been found to be 92.5, 100.76, 102.8, and 102.7° respectively for X = H, F, Cl, and Br. This suggests that repulsions between the X groups as well as electronic effects may play an important part in determining the structure of silylenes.<sup>36</sup>

The simplest silylene  $H_2Si:$  is formed by the pyrolysis of  $SiH_4$  and the higher perhydrosilanes and it undergoes two typical types of reaction: insertion and addition. Silylene readily inserts into Si–H bonds (Scheme 4) both in perhydro- and alkylsilanes (organosilanes such as  $Et_3SiH$  are often used as chemical traps for  $R_2Si:$  species).<sup>37</sup>

Silylene also undergoes nonstereospecific addition to a variety of conjugated dienes (Scheme 5).<sup>37</sup>

Diffuorosilylene is much more stable than other simple silylenes, having a half-life at room temperature of about two minutes, much longer than that of difluorocarbene (ca. 1 s), but much shorter than that of  $GeF_2$  which is a stable

Scheme 4

Scheme 5

solid. This has meant that much of the chemistry of  $F_2Si:$  has been investigated in the condensed rather than the gas phase. The silylene is readily prepared at high temperature, and in the absence of trapping agents forms oligo- and polyperfluorosilanes (equation 4).<sup>37</sup>

As in the case of  $H_2Si:$ , difluorosilylene undergoes both insertion and addition reactions (Scheme 6), although in this case there is often more than one  $SiF_2$  unit in the product, which is perhaps not surprising in view of the formation of  $Si_nF_{2n+2}$  species on condensation. Insertion reactions occur readily with fluoroalkenes, but addition occurs with other alkenes. This is presumably due to the high strength of the Si–F bond formed in the insertion which drives the reaction.<sup>37</sup>

Scheme 6

Scheme 7

Dichlorosilylene may be prepared by pyrolysis of perchloropolysilanes and again undergoes both insertion and addition reactions. The insertion into a wide variety of bonds, including C–H bonds, has been studied (Scheme 7). At the elevated temperatures used in these reactions, elimination of  $\text{H}_2$  and cyclization may also occur and, if the ring formed is strained, a further  $\text{Cl}_2\text{Si:}$  insertion may occur.<sup>37</sup>

As in the case of  $\text{F}_2\text{Si:}$ , addition of  $\text{Cl}_2\text{Si:}$  to alkenes occurs readily (Scheme 8), but the products rarely contain Si–Si bonds even if more than one Si atom is present in the product, due to dimerization.<sup>37,38</sup>

The flash photolysis of  $\text{H}_3\text{SiX}$  ( $\text{X} = \text{Cl}, \text{Br}$  or  $\text{I}$ ) gives rise to  $\text{HXS i:}$ , the structures of which have been investigated by emission and absorption spectra. Like the  $\text{X}_2\text{Si:}$  species they have a singlet ground state with a relatively small angle at silicon.<sup>30</sup> Photolysis of  $\text{H}_3\text{SiN}_3$  at 193 nm in an argon matrix at 10 K leads to the formation of  $\text{HSi}\equiv\text{N}$  that can be characterized by IR and UV spectroscopy at low temperature

but which decomposes rapidly as it is warmed.<sup>39</sup> The co-condensation of  $\text{SiO}$  and  $\text{O}_2$  in an argon matrix gives isolated, linear  $\text{SiO}_2$  molecules (quite unlike the extended array of four-coordinate silicon atoms in  $\text{SiO}_2$  in the form of quartz) having a characteristic IR band at  $1400\text{ cm}^{-1}$ .<sup>40,41</sup> The mixed chalcogen species,  $\text{SiOS}$  may also be trapped from the reaction between  $\text{SiS}$  and  $\text{O}$  atoms.<sup>42</sup>

Although the chemistry of silylenes was for many years restricted to that of reactive species where the two substituents at Si were small, since the mid 1990s the realization that steric protection of the silylene center could enable stable silylenes to be isolated under normal laboratory conditions has led to a blossoming of new chemistry. Nitrogen substituted silylenes can be prepared by reduction of halosilane precursors as shown in Scheme 9. Reagents such as potassium in THF, potassium-graphite and finely divided magnesium can be used to effect the reduction and fluoro-, chloro-, or bromosilanes may be used as precursors. Although thermally stable, these

Scheme 8

Scheme 9

Scheme 10

silylenes are reactive towards a wide range of compounds and typically undergo reactions that involve nucleophilic addition to an unsaturated organic compound, insertion into polar bonds such as O–H, C–X (X = Cl, Br or I), or N–M (M = Li, Na or K), and reactions with transition metal centers. Examples of these reactions are shown in Scheme 10. The chemistry of these and related silylenes has been the subject of many publications, these have been reviewed recently.<sup>43–46</sup>

#### 4 THREE-COORDINATE COMPOUNDS

The structural details of three-coordinate silicon compounds have, as their one- and two-coordinate analogs discussed above, mainly been obtained at either very high- or low temperatures or using very rapid spectroscopic techniques. This is due to their high reactivity and short half-lives, in turn due to the reluctance of silicon to form multiple bonds as, unlike carbon, it is usually much more thermodynamically advantageous to form two single bonds rather than one double bond to silicon. Early work on three-coordinate silicon compounds has been reviewed.<sup>30</sup> The structures of unsaturated Si–H containing compounds such as  $\text{H}_2\text{Si}=\text{SiH}_2$  and other low-coordinate species such as silylenes have been the subject of much theoretical investigation. The calculated structures of these fascinating compounds and comparisons with experimentally derived data for them are available.<sup>47</sup>

Trivalent inorganic silicon cations are extremely rare in solution (but common in the gas phase<sup>48</sup>) and their existence has remained a matter of some dispute.<sup>49–51</sup> Many

calculations on the structures and the stability of  $\text{R}_3\text{Si}^+$ ,  $\text{R}_3\text{Si}^\cdot$ , and  $\text{R}_3\text{Si}^-$  species have been carried out and are reviewed.<sup>34,51</sup> Silyl radicals,  $\text{R}_3\text{Si}^\cdot$ , and silyl anions,  $\text{R}_3\text{Si}^-$ , may be prepared, although the radicals tend to have a short half-life. The inorganic radicals  $\text{R}_3\text{Si}^\cdot$  (R = H, F or Cl) are known, although organic-substituted silyl radicals are much more common and are used for radical reductions in organic chemistry. The radicals are usually prepared by UV photolysis of  $\text{R}_3\text{Si}-\text{H}$  compounds either alone or in the presence of radical initiators such as *t*-BuOOBu-*t*, and may be observed spectroscopically in inert gas matrices at low temperatures.<sup>30</sup>

An X-ray investigation of  $\text{MSiH}_3$  (M = K, Rb, or Cs; for their preparation, see Section 5.1.3) shows that the compounds crystallize in the sodium chloride face-centered cubic lattice. This differs from the NiAs structure of  $\text{KCH}_3$  and gives an effective ionic radius for  $\text{SiH}_3^-$  of about 2.26 Å.<sup>52</sup> The most widely studied of the compounds is  $\text{KSiH}_3$ , which also has an orthorhombic  $\beta$ -form<sup>53</sup> (see Section 5.1.3 for details of its reactions). The formation and use of the  $\text{Cl}_3\text{Si}^-$  ion by treatment of  $\text{Cl}_3\text{SiH}$  with tertiary amines or from  $\text{BrSiCl}_3$  is discussed more fully in Section 5.2.3 Three-coordinate  $\text{SiOX}_2$  (X = F or Cl) are formed in an argon matrix from the photolysis of SiO and  $\text{X}_2$ <sup>41,54</sup> while  $\text{SiOCl}_2$  can be isolated in a matrix from the combustion of  $\text{SiCl}_4$  with  $\text{O}_2$ .<sup>55</sup>

Stable compounds containing simple three-coordinate silicon atoms other than the alkali metal salts were not isolated until a range of transition metal silylene complexes were prepared. However, instead of having simple structures of the type  $\text{R}_2\text{Si}=\text{ML}_n$ , that is, analogous to their carbon analogs, the silicon atom is usually further coordinated by a donor ligand such as HMPA or THF. Some donor-free complexes have, however, been prepared in solution.

Displacement of a good leaving group from silicon in a noncoordinating solvent (equation 5) allows solvent-free complexes (**1**) to be prepared when the substituents on silicon are bound via sulfur. As would be expected by analogy with carbene complexes, the  $^{29}\text{Si}$  NMR chemical shift for these complexes is at very low field (264.4 and 268.7 ppm, respectively, for  $\text{R} = \text{S-}i\text{-p-tolyl}$  and  $\text{SEt}$ , respectively) and they also react readily with donor molecules such as MeCN to give four-coordinate, donor stabilized silylene species.<sup>56,57</sup> (See Section 6 below for further details of transition metal silyl complexes.)

The salt elimination method (equation 6) may also be used to prepare silylene complexes and, again if sulfur ligands are present, a donor-free complex may be formed as shown, although it is only the minor product along with the donor stabilized complex (**2**) which it readily forms in the presence of excess HMPA. The donor-free complex is only stable below  $-30^\circ\text{C}$  and decomposes above this temperature to give  $\text{HFe}_3(\text{CO})_{11}^-$  and the polysilane  $[(t\text{-BuS})_2\text{Si}]_n$ .<sup>58</sup>

## 5 FOUR-COORDINATE COMPOUNDS

The chemistry of silicon is largely that of four-coordinate compounds although, as seen in Section 7, higher coordination is readily achieved and many stable compounds containing five- and six-coordinate silicon are known. Silicon forms unusually strong bonds to the electronegative elements such as the halogens, oxygen, and nitrogen; Table 2 shows typical bond energies in some representative four-coordinate compounds. The bonds to the halogens and to oxygen are even stronger than their carbon analogs, but, as will be seen in the following section, compounds containing such bonds are also usually much more reactive than their carbon analogs.

**Table 2** Average covalent bond strengths and lengths in silicon compounds<sup>59,60</sup>

|       | Bond strength ( $\text{kJ mol}^{-1}$ ) | Bond length ( $\text{\AA}$ ) |
|-------|----------------------------------------|------------------------------|
| Si-H  | 326                                    | 1.48                         |
| Si-F  | 582                                    | 1.55                         |
| Si-Cl | 391                                    | 2.02                         |
| Si-C  | 301                                    | 1.87                         |

### 5.1 Perhydrosilanes

Although the chemistry of carbon, the near neighbor of silicon in the periodic table, is greatly dominated by the vast array of compounds containing C-H bonds, there are far fewer comparable silicon species. Generally speaking, the simple alkanes are rather unreactive and, even in more complicated compounds containing other functional groups, the C-H bonds are likely, along with C-C bonds, to be the least reactive in the molecule. Compounds containing Si-H bonds do not occur naturally and this is due to the high reactivity of the Si-H bond toward a wide variety of reagents. The Si-O bond is very strong and its formation is often the overriding factor in many reactions, and many of the compounds described in Section 6, including the hydrides, react with water or dilute aqueous acid or base to give Si-O containing products. Why then is the chemistry of silanes so different from that of alkanes? An important difference between carbon and silicon is their electronegativity, 2.5 and 1.8 (on the Pauling scale), respectively. The rather greater electropositive character of silicon means that in contrast to carbon, in which the C-H bond is polarized  $\text{C}^{\delta-}-\text{H}^{\delta+}$ , the Si-H bond is polarized in the opposite manner  $\text{Si}^{\delta+}-\text{H}^{\delta-}$ . This, combined with the relatively high ionic character of the Si-H bond, and the fact that it is about  $90 \text{ kJ mol}^{-1}$  weaker than the C-H bond, means that Si-H compounds are much more reactive than their carbon analogs. The Si-H bond also has greater ionic character than the C-H bond. The availability of d-orbitals on silicon means that five- or six-coordinate intermediates or transition states are readily accessible, and the larger size of silicon also means that incoming reagents have more space in which to attack than in comparable carbon compounds. The chemical and physical properties of hydrosilanes are discussed in detail elsewhere.<sup>61,62</sup>

#### 5.1.1 Preparation of Silicon Hydrides

Several methods are available for the preparation of compounds containing Si-H bonds. Historically, the silicon hydrides  $\text{H}(\text{SiH}_2)_n\text{H}$  ( $n = 1, 2, 3$ , etc.) were prepared by reaction of various metal silicides (such as those of Mg, Al, and Fe) with hydrochloric or phosphoric acid (equation 7).<sup>63</sup> For example,  $\text{Mg}_2\text{Si}$  addition to dilute phosphoric acid affords  $\text{H}_4\text{Si}$ ,  $\text{H}_3\text{SiSiH}_3$ ,  $\text{H}_3\text{SiSiH}_2\text{SiH}_3$ ,  $\text{Si}_4\text{H}_{10}$ , and  $\text{Si}_5\text{H}_{12}$  (together

Scheme 11

with higher silanes) in an approximate ratio 8:6:3:2:1 but with only a 25% overall conversion of silicide to silane silicon. The yields from this type of reaction are low because of the hydrolysis of the Si–H bonds in the products by the aqueous environment. Better yields are obtained by treatment of Mg<sub>2</sub>Si with NH<sub>4</sub>Br in liquid ammonia (for the detailed preparation of silane from NH<sub>4</sub>Br and Mg<sub>2</sub>Si, see Brauer<sup>64</sup>) or with H<sub>2</sub>NNH<sub>2</sub>·2HCl in hydrazine. More recent analysis of the products from this type of reaction show that silanes containing up to nine silicon atoms are formed.<sup>65</sup>

These methods are no longer used because the separation of the mixtures formed leads to low yields of the individual silanes. A far more general method, and one that can conveniently be carried out on a laboratory scale, is the reduction of halosilanes using reagents such as LiAlH<sub>4</sub> or LiH (Scheme 11). Unfortunately, polyhalides cannot be partially reduced in this way, that is, SiCl<sub>4</sub> cannot be reduced to H<sub>2</sub>SiCl<sub>2</sub>. Silyl deuterides, Si<sub>n</sub>D<sub>2n+2</sub>, can be prepared in similar ways to the hydrides, that is, by D<sub>2</sub>O/DCI decomposition of Mg<sub>2</sub>Si or by reduction of halides with LiAlD<sub>4</sub>.

Disilane, H<sub>6</sub>Si<sub>2</sub>, has also been produced cleanly by CO<sub>2</sub> laser irradiation of monosilane SiH<sub>4</sub><sup>66</sup> and a detailed procedure for the preparation of disilane, trisilane, and higher silanes by passage of an electric discharge through SiH<sub>4</sub> has also been reported.<sup>67</sup> Physical data for some silanes are given in Table 3 and, as would be expected by analogy with the alkanes, the small silanes are volatile gases and the larger ones are

liquids with boiling points that increase as the molecular weight increases. Further properties of the higher silanes (NMR and Raman spectra, viscosity, and surface tension) are available,<sup>68–70</sup> and the physical and thermodynamic properties of SiH<sub>4</sub> have been reviewed.<sup>71</sup> There are also reviews of the manufacture and applications of SiH<sub>4</sub><sup>62,72</sup> and of the methods associated with analysis and purification of SiH<sub>4</sub>.<sup>62,73</sup>

### 5.1.2 Structure of Perhydrosilanes

The structure of H<sub>4</sub>Si and D<sub>4</sub>Si has been investigated in the gas phase. Tetrahedral geometry is found as expected and the bond lengths are 1.49 and 1.47 Å, respectively, for the H and D compounds.<sup>75</sup> The structure of H<sub>3</sub>SiSiH<sub>3</sub> has been determined by electron diffraction in the gas phase and shows an Si–Si bond length of 2.331 Å (which is slightly shorter than that found in elemental Si and in Si<sub>2</sub>Me<sub>6</sub>), an Si–H bond length of 1.492 Å, and an H–Si–Si angle of 101.3°. <sup>76</sup> Calculations on the structure of SiH<sub>4</sub> and related silanes are discussed in References 35 and 77.

### 5.1.3 Reactions of Perhydrosilanes

The perhydrosilanes are toxic and spontaneously flammable in air and form explosive mixtures with oxygen. The mechanism of SiH<sub>4</sub>/O<sub>2</sub> explosions has been investigated, and the products from such reactions depend greatly on the initial composition of the mixture. For mixtures >70% O<sub>2</sub>, the products are SiO<sub>2</sub> and H<sub>2</sub>O, but for mixtures >70% SiH<sub>4</sub>, the products are SiO<sub>x</sub> (SiO deposited may be a mixture of SiO<sub>2</sub> and Si), Si, and H<sub>2</sub>.<sup>78</sup> Extreme caution should, therefore, be exercised in their handling. Accidental release of silane into the atmosphere may lead to fire or explosion hazards, and spontaneous ignition of a SiH<sub>4</sub>/N<sub>2</sub> mixture in air may occur above about 2.5 volume % SiH<sub>4</sub>. (The problems associated with handling silane have been addressed.<sup>79</sup>) As has been stated above, highly pure silane undergoes thermal decomposition at about 570–670 °C to give highly pure silicon, and SiH<sub>4</sub> has therefore become an important gas used in the manufacture of integrated circuits and photovoltaic cells. There has been considerable discussion about the mechanisms of the plasma or thermal chemical vapor deposition of Si from SiH<sub>4</sub>. Much work has suggested that the silyl radical SiH<sub>3</sub>· is the dominant species responsible for deposition, but more recent work suggests that silylene, H<sub>2</sub>Si:, is the most important species which, together with disilane (which is formed by insertion reaction as shown below), when adsorbed on to a surface, breaks down to give silicon.<sup>80,81</sup> The mechanism of deposition may also involve the adsorption of H<sub>2</sub>Si: on to a surface and then insertion of further H<sub>2</sub>Si: units into the Si–H bonds of the absorbed species; further insertions and loss of H<sub>2</sub> lead to the buildup of material containing Si–Si bonds (Scheme 12).<sup>82</sup> The use of SiH<sub>4</sub> and chlorosilanes for the deposition of Si has been discussed<sup>83</sup> and the reactions of SiH<sub>4</sub> to form transition metal complexes are described in Section 6.1. The ionization and

Scheme 12

ensuing fragmentation of  $\text{SiH}_4$  gives  $\text{SiH}_x^{+\cdot}$  (where  $x = 1, 2$ , or  $3$ ) that can undergo hydride exchange reactions or clustering with neutral  $\text{SiH}_4$ . Reactions of these ions with inorganic and organic compounds have been reviewed.<sup>29</sup>

As stated above, the most obvious reaction of silanes is their oxidation by, for example, oxygen, water, and alcohols (in great contrast to the analogous alkanes). From this it follows that silanes are good reducing agents and organosilicon compounds (which are much easier to handle than the perhydro compounds) such as  $\text{Et}_3\text{SiH}$  have been used extensively to carry out reductions in organic chemistry. (For reductions in organic chemistry using  $(\text{EtO})_3\text{SiH}$ , see Fieser.<sup>84</sup>) Although silanes do not appear to react with pure water or slightly acidic water under normal conditions, in slightly basic solution rapid and complete hydrolysis occurs with the evolution of hydrogen. The hydrolytic cleavage of a Si–Si bond also affords  $\text{H}_2$ , and this method can therefore be used to ascertain the number of Si–H and Si–Si bonds present in a molecule by measuring the volume of hydrogen evolved (Scheme 13).

Silane reacts with methanol to give the alkoxysilanes  $(\text{MeO})_n\text{SiH}_{4-n}$  ( $n = 2, 3, 4$ ) and with higher alcohols in the presence of base to give tetraalkoxysilanes (equation 8).<sup>85</sup> This type of reaction is, however, rarely carried out as the alkoxysilanes produced are more conveniently prepared from alcohols and  $\text{SiCl}_4$  (which is more readily available than  $\text{SiH}_4$  and much more easily handled). Similarly, silyl esters,  $\text{Si}(\text{OCOR})_4$ , are also usually prepared from polyhalogenosilanes rather than from silane and a carboxylic acid.

Silane reacts with alkali metals (Na, K, Rb, and Cs) over a period of between about a week for Cs, and two or three months for Na, to give  $\text{H}_3\text{SiM}$  species (see Section 4 for a description of their structures) in the ether solvents  $\text{MeOCH}_2\text{CH}_2\text{OMe}$  or  $(\text{MeOCH}_2\text{CH}_2)_2\text{O}$  by two different pathways depending on the stoichiometry of the reagents (Scheme 14).<sup>86,87</sup>

Scheme 13

Scheme 14

Scheme 15

The most well known of the alkali metal derivatives is  $\text{KSiH}_3$ , which acts as a nucleophile in a wide range of displacement reactions, for example, with  $\text{HCl}$  to give  $\text{SiH}_4$  and  $\text{KCl}$ , with  $\text{MeCl}$  to give  $\text{H}_3\text{SiCH}_3$ ,<sup>88</sup> and with  $\text{PhCH}_2\text{Cl}$  to give  $\text{PhCH}_2\text{SiH}_3$ ,<sup>89</sup> or as a reducing agent, for example, reducing  $\text{CO}_2$  to  $\text{CO}$ .<sup>90</sup> Silylpotassium reacts with various other halides to give silyl substituted products and a range of such reactions are depicted in Scheme 15.<sup>91,92</sup>

The reactions between  $\text{KSiH}_3$  and perhydrosilanes (equation 9) afford various other silylpotassium reagents, which have also been used to prepare other functional oligosilanes in a manner similar to that shown in Scheme 15.<sup>93,94</sup>

## 5.2 Silicon Halohydrosilanes, $\text{H}_n\text{SiX}_{4-n}$ ( $n = 1-3$ , $\text{X} = \text{Halogen}$ ), etc.

These compounds are highly reactive like the perhydrosilanes and must be handled with care because of their ready hydrolysis in the atmosphere to give the corrosive and toxic hydrogen halides,  $\text{HX}$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{ or } \text{I}$ ). Again, this high reactivity is in great contrast to the relative inertness of common halohydroalkanes such as  $\text{CH}_2\text{Cl}_2$  and  $\text{CHCl}_3$ . Of all the halohydrosilanes, trichlorosilane is by far the most important and the most widely studied because of its industrial uses, for example, in the preparation of high purity silicon as discussed earlier in Section 1.1 and in the preparation of organosilanes via the *Hydrosilation Catalysis* reaction.

### 5.2.1 Preparation of Halohydrosilanes

Trichlorosilane is produced and used on a large industrial scale and it is usually prepared from the reaction of Si with  $\text{HCl}$  at about  $300^\circ\text{C}$ , which can also give  $\text{H}_2\text{SiCl}_2$ .<sup>95</sup> The

preparation of  $\text{SiHBr}_3$  and  $\text{SiH}_2\text{Br}_2$  can be achieved in a similar manner from Si and HBr.<sup>96</sup> At 360 °C and above, Si reacts with HBr to give  $\text{SiHBr}_3$  and  $\text{SiBr}_4$  in varying proportions depending on the temperature, a higher temperature giving a greater proportion of  $\text{SiBr}_4$ .<sup>97</sup> Silicon tetrachloride can also be reduced with hydrogen to give  $\text{SiHCl}_3$  (equation 10).<sup>98</sup>

The monohalo- and the dihalosilanes  $\text{H}_3\text{SiX}$  and  $\text{H}_2\text{SiX}_2$  ( $\text{X} = \text{Cl}, \text{Br}$  or  $\text{I}$ ) may be prepared by the reaction between silane and one or two equivalents of HX respectively, catalyzed by the corresponding aluminum halide (equation 11).

The fluorosilane  $\text{H}_3\text{SiF}$  cannot be prepared in this way but is readily available by halogen exchange reactions from, for example, the reaction between  $\text{SbF}_3$  and  $\text{H}_3\text{SiCl}$ . The other fluorohydrosilanes  $\text{H}_2\text{SiF}_2$  and  $\text{HSiF}_3$  are similarly prepared by treatment of the corresponding chloro or bromo compound with a metal fluoride, for example, heating  $\text{SiHCl}_3$  with  $\text{TiF}_4$  at 100 to 200 °C affords  $\text{HSiF}_3$ .<sup>99</sup>

The iodosilane  $\text{H}_2\text{SiI}_2$  can be prepared by cleavage of the Si–Ph bonds in  $\text{Ph}_2\text{SiH}_2$  with  $\text{HI}$ <sup>100</sup> or more conveniently by treating  $\text{PhSiH}_3$  with  $\text{I}_2$  (Scheme 16).<sup>101</sup> (Cleavage of  $\text{PhSiH}_3$  with HBr or HI similarly gives  $\text{H}_3\text{SiBr}$  or  $\text{H}_3\text{SiI}$ .<sup>102,103</sup>)

Aryl groups such as Ph, *p*-tolyl, and  $\alpha$ -naphthyl are all readily cleaved from silicon by HX/ $\text{AlX}_3$  to give a variety of halohydrodisilanes (Scheme 17).<sup>104</sup> Similarly, an extensive range of halotrisilanes including most of the possible isomers of  $\text{Si}_3\text{X}_7\text{H}$ ,  $\text{Si}_3\text{X}_6\text{H}_2$ ,  $\text{Si}_3\text{X}_5\text{H}_3$  ( $\text{X} = \text{Cl}, \text{Br}$  or  $\text{I}$ ),  $\text{Si}_3\text{I}_4\text{H}_4$ ,  $\text{Si}_3\text{I}_3\text{H}_5$ , and  $\text{Si}_3\text{I}_2\text{H}_6$ , can be prepared by cleavage of the Si–aryl bonds of corresponding arylsilanes using HX. Detailed NMR spectroscopic studies of these compounds have been carried out.<sup>105</sup>

Compounds containing Si–H bonds generally react readily with halogens;  $\text{SiH}_4$  with  $\text{Cl}_2$  or  $\text{Br}_2$  gives explosive reactions

Scheme 16

Scheme 17

but the vigor of these reactions is ameliorated at low temperature, and  $\text{H}_3\text{SiBr}$  and  $\text{SiH}_2\text{Br}_2$  may be isolated from such reactions (equation 12).<sup>106,107</sup>

The reaction of hydrogen halides with disilane gives halodisilanes but these, apart from  $\text{IH}_2\text{SiSiH}_3$ , tend to disproportionate. Reactions of the higher silanes with halogens also afford halohydrosilanes but such reactions are often accompanied by Si–Si bond cleavage; for example, the reaction of disilane with iodine gives not only  $\text{H}_3\text{SiSiH}_2\text{I}$ ,  $\text{H}_3\text{SiSiH}_2\text{I}_2$ , and  $\text{H}_2\text{ISiSiH}_2\text{I}$  but also  $\text{SiH}_2\text{I}_2$  and  $\text{SiHI}_3$  in significant yield.<sup>108</sup> For further details and discussion of this type of preparation, see MacDiarmid.<sup>109,110</sup> The triiodide can also usefully be prepared using the high reactivity of the Si–N bond, as shown in Scheme 18.<sup>109,110</sup>

The physical properties of some halohydrosilanes are shown in Table 4 and, as in the case of the perhydrosilanes, the compounds containing a small number of the lighter halogens

Scheme 18

are gases at room temperature and pressure while the others are liquids.

### 5.2.2 Structure of Halohydrosilanes

The molecular structures of several halohydrosilanes are known, and some of the structural parameters for them are shown in Table 5.

The structures of  $\text{H}_3\text{SiF}$  and  $\text{H}_3\text{SiI}$  in the solid state show clear intermolecular interactions. The molecules form chains (Figure 3), with both  $\text{Si} \cdots \text{F}$  and  $\text{Si} \cdots \text{I}$  distances being less than the sum of the respective van der Waals radii.<sup>120</sup>

### 5.2.3 Reactions of Halohydrosilanes

The halohydrosilanes disproportionate on heating as shown in Scheme 2 and react rapidly with protic reagents such as water, alcohols, and amines to give compounds containing Si–O and Si–N bonds, respectively. In the hydrolysis of such species the halogen is removed first (as HX) giving a hydroxysilane, for example,  $\text{H}_3\text{SiOH}$ , which then undergoes condensation to give a siloxane, for example,  $\text{H}_3\text{SiOSiH}_3$ , and finally the Si–H groups are hydrolyzed. Careful hydrolysis of  $\text{Cl}_3\text{SiH}$  affords a mixture of oligomeric silsesquioxanes of

<sup>a</sup>E = electron diffraction; M = microwave; X = X-ray diffraction; MO = molecular orbital calculations.

**Figure 3** The chain structure of  $\text{H}_3\text{SiX}$  (X = F or I)

**Scheme 19**

general formula  $(\text{HSiO}_{1.5})_n$  ( $n = 4-7$ ),<sup>121</sup> the structures of which are described in Section 5.5.1.

One of the most widely studied of the reactions of trichlorosilane is its interaction with tertiary amines in acetonitrile to give appreciable concentrations of  $\text{Cl}_3\text{Si}^-$  in solution, as shown in Scheme 19.<sup>122</sup>

The silyl anion,  $\text{Cl}_3\text{Si}^-$ , has been widely studied and reacts with a variety of compounds. The  $\text{Cl}_3\text{SiH}/\text{R}_3\text{N}$  system allows additions to multiple bonds (insertion into the Si–H bond, equation 13) and the formation of organosilicon compounds via the hydrosilation reaction.<sup>122</sup>

The trichlorosilyl anion also reacts with organic halides in several ways, the simplest of which involves substitution of the halide by an  $\text{SiCl}_3$  group (Scheme 20).<sup>122</sup>

Unfortunately, organic halides with three or more chlorines on the same carbon undergo more complicated reactions with  $\text{Cl}_3\text{Si}^-$  and tend to give  $\text{SiCl}_4$  as the main silicon-containing product.<sup>122</sup> With carbonyl compounds a so-called ‘reductive silylation’ occurs, in which the carbonyl oxygen is lost from the organic compound and is substituted by a  $\text{Cl}_3\text{Si}$  group and an H (Scheme 21).

In the reaction of  $\text{Cl}_3\text{Si}^-$  with acid chlorides, two trichlorosilyl groups are introduced (equation 14); this probably proceeds via a two-step mechanism. The first step involves reductive silylation and loss of the carbonyl group; the second involves a halide displacement as above. These trichlorosilyl compounds may be further treated with Grignard

**Scheme 20**

Scheme 21

Scheme 22

Scheme 23

or lithium reagents to give tetraorganosilanes.<sup>122</sup>

The strength of the Si–O (and the Si–S) bond and the stability of the  $\text{Cl}_3\text{Si}^-$  anion also allow the reduction of  $\text{P}^{\text{V}}$  to  $\text{P}^{\text{III}}$  compounds,  $\text{S}^{\text{IV}}$  to  $\text{S}^{\text{II}}$  compounds, and amine oxides to

amines with either  $\text{Cl}_3\text{SiSiCl}_3$  (or in some cases  $\text{SiHCl}_3/\text{R}_3\text{N}$ ) in benzene or chloroform solution under mild conditions (Schemes 22 and 23).<sup>123–126</sup> The silicon-containing products are  $\text{SiCl}_4$ ,  $\text{Cl}_3\text{SiXSicl}_3$  ( $\text{X} = \text{O}$  or  $\text{S}$ ), and  $(\text{XSicl}_2)_n$  ( $\text{X} = \text{O}$  or  $\text{S}$ ).

This type of reaction proceeds by a radical mechanism and the product distribution is very dependent on the R groups. Primary acetates give very predominantly ethers, secondary acetates give mixtures, and tertiary acetates give alkane as the exclusive product (Scheme 23).<sup>127–129</sup>

### 5.3 Tetrahalosilanes

The perhalosilanes  $\text{X}_4\text{Si}$  ( $\text{X} = \text{F}$ ,  $\text{Cl}$ ,  $\text{Br}$ , or  $\text{I}$ ), the higher perhalosilanes, and compounds containing mixtures of halogens are all reactive compounds (as would be expected from the chemistry of the halohydrosilanes described above in Section 5.2.3) that hydrolyze readily to give  $\text{HX}$  in the atmosphere; they therefore require care in handling, preferably under a blanket of inert gas. The chloride  $\text{Cl}_4\text{Si}$  is by far the most widely used of these compounds and is available on a large scale.

#### 5.3.1 Preparations of Perhalosilanes

The silicon tetrahalides  $\text{SiX}_4$  may all be obtained by direct combination of the elements (equation 15). Silicon inflames in fluorine at room temperature to give  $\text{SiF}_4$ , but heating is required to bring about reactions with the other halogens; iodine vapor passed over silicon above  $600^\circ\text{C}$  gives  $\text{SiI}_4$ . More conveniently, on a laboratory scale, cleavage of Si–aryl bonds may be used for synthesis, for example, reaction of  $\text{PhSiH}_3$  with  $\text{Br}_2$  affords  $\text{PhSiBr}_3$ , which when treated with  $\text{HBr}/\text{AlBr}_3$  in benzene gives a near quantitative yield of  $\text{SiBr}_4$ .<sup>130</sup> A mixture of  $\text{Cl}_2$  and  $\text{Br}_2$  over  $\text{Si}$  at  $700^\circ\text{C}$  affords the mixed halosilanes  $\text{SiCl}_n\text{Br}_{4-n}$  ( $n = 1–3$ ),<sup>110</sup> as do the pyridine catalyzed redistribution reactions between  $\text{SiCl}_4$  and  $\text{SiBr}_4$ .<sup>131</sup>

Mixed tetrahalosilanes may be prepared by halogenation of a hydrohalosilane and by reaction of a tetrahalosilane with  $\text{HX}$  (Scheme 24). For example,  $\text{SiHCl}_3$  is formed from  $\text{I}_2$  and  $\text{HSiCl}_3$  and this subsequently reacts with the  $\text{HI}$  produced in the reaction to give  $\text{SiI}_2\text{Cl}_2$ .<sup>132</sup>

Redistribution reactions also readily occur, for example, mixtures of  $\text{SiCl}_4$  and  $\text{SiI}_4$  in the presence of pyridine afford

Scheme 24

statistical mixtures of  $\text{SiCl}_n\text{I}_{4-n}$  ( $n = 0-4$ ) under reflux at  $61^\circ\text{C}$ .<sup>133</sup> Tetrafluorosilane reacts with  $\text{MgCl}_2$  and  $\text{AlCl}_3$  to give  $\text{SiCl}_4$  and the mixed  $\text{SiF}_n\text{Cl}_{4-n}$  ( $n = 1-3$ ).<sup>134</sup>  $\text{HSiI}_3$  undergoes halogen exchange reactions with, for example,  $\text{SiFBr}_3$  to give  $\text{SiFBr}_2\text{I}$ ,  $\text{SiFBr}_2\text{I}$ ,  $\text{SiFBrI}_2$ , and  $\text{SiFI}_3$ .<sup>135</sup>

Hexafluorodisilane may be prepared by halogen exchange reactions of  $\text{Si}_2\text{Cl}_6$  or  $\text{Si}_2\text{Br}_6$  with a variety of metal fluorides but better yields (70–80%) may be obtained from the reaction between  $(\text{MeO})_3\text{SiSi}(\text{OMe})_3$  and  $\text{BF}_3$  in a sealed bomb at room temperature (equation 16).<sup>136</sup>

The reaction of Si with  $\text{SiF}_4$  at  $1150^\circ\text{C}$  and low pressure gives  $(\text{SiF}_2)_n$  polymer which, if heated under vacuum at 200 to  $350^\circ\text{C}$ , breaks down to give perfluorosilanes  $\text{Si}_n\text{F}_{2n+2}$  where  $n$  is from 1 to 14 or more. The polymer is also broken down by aqueous HF to give silanes  $\text{Si}_n\text{H}_{2n+2}$  ( $n = 1-6$ ).<sup>137</sup> The cleavage of  $\text{Si}_2\text{F}_6$  with  $\text{Br}_2$  affords  $\text{SiF}_3\text{Br}$  and  $\text{SiF}_2\text{Br}_2$ , while the fluorination of  $\text{SiBr}_4$  with  $\text{SbF}_3$  affords all three of the mixed halides.<sup>138</sup> Reaction of  $[(\text{MeO})_3\text{Si}]_2\text{Si}(\text{OMe})_2$  with  $\text{BF}_3$  in a sealed tube also gives  $(\text{F}_3\text{Si})_2\text{SiF}_2$  in a manner similar to equation (16).<sup>139</sup> Silicon tetraiodide when treated with silver powder at  $208^\circ\text{C}$  gives  $\text{I}_3\text{SiSiI}_3$ .<sup>140</sup> The reaction between  $\text{Si}_2\text{Cl}_6$  and  $\text{Me}_3\text{N}$  gives perchlorooligosilanes (equation 17), the exact product isolated, such as  $\text{Si}_5\text{Cl}_{12}$  and  $\text{Si}_6\text{Cl}_{14}$ , being dependent on the stoichiometry of the reagents used, and whether the volatile  $\text{SiCl}_4$  formed as a coproduct is removed continuously from the reaction mixture.<sup>141</sup>

This type of synthesis has clear advantages over the direct combination of elements method which gives complicated mixtures that need to be separated.<sup>141</sup> The higher perchlorosilanes  $\text{Cl}_3\text{Si}(\text{SiCl}_2)_n\text{SiCl}_3$  ( $n = 1-6$ ) can be prepared in low yield, along with  $\text{SiCl}_4$ , by passing chlorine over a mixture of  $\text{CaSi}_2$  and  $\text{FeSi}_2$  at 120 to  $150^\circ\text{C}$ .<sup>142</sup> Perhalogenated silanes may also readily be made by cleavage of phenyl groups by  $\text{HX}/\text{AlX}_3$  ( $\text{X} = \text{Cl}, \text{Br}$  or  $\text{I}$ ) from either cyclic or acyclic perphenyl compounds (Scheme 25). The preparations and reactions of hydro- and halosilanes containing Si–Si bonds are discussed in more detail by Hengge.<sup>143</sup>

Straight chain perhalooligosilanes may also be prepared from the cyclic phenyl compounds by cleaving the ring first

Scheme 25

Scheme 26

Scheme 27

with halogen and subsequently cleaving the Si–Ph bonds with  $\text{HX}/\text{AlX}_3$  (equation 18).<sup>144–146</sup>

The *neo*-pentasilane  $(\text{Cl}_3\text{Si})_4\text{Si}$  is formed along with  $\text{SiCl}_4$ ,  $\text{Si}_2\text{Cl}_6$ ,  $\text{Si}_3\text{Cl}_8$ , and  $\text{Si}_4\text{Cl}_{10}$  on mercury sensitized photolysis of  $\text{Cl}_3\text{SiH}$ <sup>147</sup> or by base-catalyzed disproportionation of  $\text{Si}_2\text{Cl}_6$  or  $\text{Si}_3\text{Cl}_8$  (Scheme 26).<sup>141,148</sup>

Ligand redistribution reactions occur when  $\text{Si}_2\text{Cl}_6$  and  $\text{Si}_2\text{Br}_6$  are heated together at  $100^\circ\text{C}$  in a sealed tube, to give all of the mixed halodisilanes  $\text{Si}_2\text{Cl}_n\text{Br}_{6-n}$  ( $n = 1-5$ ). Unfortunately, the compounds cannot be separated by vacuum distillation because of further redistribution reactions. The mixed halide,  $\text{Br}_3\text{SiSiCl}_3$ , can be obtained pure by cleaving the Ph groups from  $\text{Cl}_3\text{SiSiPh}_3$  using  $\text{HBr}/\text{AlBr}_3$ .<sup>149</sup> Reaction of  $\text{BrSiCl}_3$  with the very hindered aryllithium reagent 2,4,6-*t*- $\text{Bu}_3\text{C}_6\text{H}_2\text{Li}$  at  $-78^\circ\text{C}$  leads to lithium/halogen exchange and formation of  $\text{LiSiCl}_3$ , which has a surprisingly long half-life at room temperature in THF/ $\text{Et}_2\text{O}$  of about 62 h. Little seems to have been done with  $\text{LiSiCl}_3$ , which could be a valuable reagent for the introduction of  $\text{Cl}_3\text{Si}$  groups.<sup>150</sup>

The tetrasilanes (3) react with  $t\text{-Bu}_2\text{Hg}$  to give the corresponding silylmercury derivatives, which break down on photolysis to give octasilanes (Scheme 27).<sup>151</sup>

### 5.3.2 Reactions of Perhalosilanes

Silicon halides (especially the readily available chlorides) are probably the most synthetically useful and versatile monomeric inorganic silicon compounds. They may readily be reduced to hydrides, hydrolyzed to silanols (and subsequently to siloxanes), treated with other protic species such as alcohols, carboxylic acids, amines, and thiols to give Si–OR, Si–OC(O)R, Si–NR<sub>2</sub>, and Si–SR species respectively, used to make silyl pseudohalogen derivatives by treatment with silver or alkali metal salts, for example, treated with sodium

derivatives of Group 15 elements to give Si–N, Si–P, or Si–As containing compounds, and form a wide range of adducts with amines, phosphines, and so on. They are also one of the main starting materials used for the formation of organosilicon compounds by using, for example, Grignard or organolithium compounds (see **Silicon: Organosilicon Chemistry**). The reduction of silicon halides to give silicon hydrides is discussed in Section 5.1.1 and the reactions of halosilanes to give compounds containing Si–O and Si–N bonds are found in Sections 5.5.1 and 5.6.1.

All of the SiX<sub>4</sub> tetrahalides except the fluoride hydrolyze rapidly to give hydrated silica; the fluoride also undergoes partial hydrolysis but also forms the hexafluorosilicate ion (equation 19).

Careful hydrolysis of SiCl<sub>4</sub> at –78 °C affords (Cl<sub>3</sub>Si)<sub>2</sub>O and higher chlorinated siloxanes, Cl<sub>3</sub>Si(OSiCl<sub>2</sub>)<sub>n</sub>OSiCl<sub>3</sub> (*n* = 1–5), as high boiling liquids.<sup>152</sup> These are formed by initial formation of Cl<sub>3</sub>SiOH which rapidly condenses to give the disiloxane (Cl<sub>3</sub>Si)<sub>2</sub>O which may react further with Cl<sub>3</sub>SiOH to give the higher siloxanes. (Cl<sub>3</sub>Si)<sub>2</sub>O may also be prepared by the reaction of SiCl<sub>4</sub> with O<sub>2</sub> at 960 to 990 °C.<sup>153</sup> The cyclic dimer (Cl<sub>2</sub>SiO)<sub>2</sub> is not formed, unlike the S analog. The passage of a mixture of Br<sub>2</sub> and O<sub>2</sub> over Si at 700 °C affords bromosiloxanes such as (Br<sub>3</sub>Si)<sub>2</sub>O and (Br<sub>2</sub>SiO)<sub>4</sub>; they are also formed on treatment of SiBr<sub>4</sub> with O<sub>2</sub> at 670 to 695 °C.<sup>154</sup> Reaction of SiCl<sub>4</sub> with H<sub>2</sub>S at 900 to 950 °C affords Cl<sub>3</sub>SiSH which can be distilled (unlike its oxygen analog Cl<sub>3</sub>SiOH) at 95 °C at atmospheric pressure. The pure thiol does undergo condensation at high temperature to give (Cl<sub>3</sub>Si)<sub>2</sub>S, the cyclic compound (Cl<sub>2</sub>SiS)<sub>2</sub>, and (SiCl<sub>2</sub>S)<sub>n</sub> polymer.<sup>155</sup> The reaction between SiCl<sub>4</sub> and AgS at 230 to 250 °C also affords (Cl<sub>3</sub>Si)<sub>2</sub>S.<sup>156</sup> The reaction between SiCl<sub>4</sub> and NEt<sub>4</sub>SH affords NEt<sub>4</sub>[SiSCl<sub>3</sub>], which contains four-coordinate near-tetrahedral SiCl<sub>3</sub>S units.<sup>157</sup>

The higher chlorosilanes, like SiCl<sub>4</sub>, all hydrolyze readily and react with protic species; for example, (Cl<sub>3</sub>Si)<sub>2</sub>SiCl<sub>2</sub> reacts with MeOH/Et<sub>3</sub>N to give [(MeO)<sub>3</sub>Si]<sub>2</sub>Si(OMe)<sub>2</sub> and with Me<sub>2</sub>NH to give [(Me<sub>2</sub>N)<sub>3</sub>Si]<sub>2</sub>Si(NMe<sub>2</sub>)<sub>2</sub>.<sup>158</sup> The *neo*-pentasilane (Cl<sub>3</sub>Si)<sub>4</sub>Si reacts with HCl to give the tetrasilane (4) and with MeOH to give (5) or (6) and (7) depending on the reaction conditions (Scheme 28). Compounds (6) and (7) react with BCl<sub>3</sub> or BF<sub>3</sub> to afford the corresponding halosilanes.<sup>159–161</sup>

The formation of the strong Si–O bond and an insoluble product (silica) occurs in the reaction between SiCl<sub>4</sub> and amines and acids to give amides (equation 20).<sup>162</sup>

The reaction of SiCl<sub>4</sub> with NaI in acetonitrile gives Cl<sub>3</sub>SiI (Scheme 29), which is used in situ to cleave ethers to give

Scheme 28

Scheme 29

(after hydrolysis of the initially formed silyl ether) alcohols and phenols.<sup>163</sup>

Silicon tetrafluoride reacts with epoxides in the presence of a tertiary amine to give fluorohydrins by a mechanism that probably involves five- or six-coordinate silicon species (equation 21).<sup>164</sup> The ionization of SiF<sub>4</sub> by electron impact affords SiF<sub>x</sub><sup>+</sup> (where *x* = 1, 2, or 3), which can form clusters with neutral SiF<sub>4</sub> and react with a range of small inorganic molecules.<sup>29,165</sup>

### 5.3.3 Structures of Perhalosilanes

The simple tetrahalides SiX<sub>4</sub> are tetrahedral, and bond lengths increase as the halogen gets larger. Some structural details for perhalosilanes are given in Table 6.

## 5.4 Silyl Pseudohalides

As might be expected, the silyl pseudohalides have chemical properties similar to the silyl halides although the structures of the pseudohalides have been studied in more detail and have been shown to be both interesting and novel.

**Table 6** Structural data for tetrahalosilanes

<sup>b</sup>For a discussion of the crystallization of SiI<sub>4</sub> see Kihara.<sup>172</sup>

#### 5.4.1 Silyl Isocyanates and Isothiocyanates

Silyl isocyanates can readily be prepared by treatment of chlorosilanes (bromo- or iodosilanes would also work but are less readily available) with metal cyanates. With simple halosilanes the product is always the isocyanate isomer although in the case of highly sterically hindered organosilanes, normal cyanates (which thermally isomerize to isocyanates) may be formed using silver cyanate.<sup>173</sup> Thus Si(NCO)<sub>4</sub> is formed from the reaction between SiCl<sub>4</sub> and KOCN in liquid SO<sub>2</sub>, AgOCN in C<sub>6</sub>H<sub>6</sub>, or Pb(OCN)<sub>2</sub> in C<sub>6</sub>H<sub>6</sub>.<sup>174,175</sup> Similarly, Si(NCS)<sub>4</sub> is formed in the reaction between SiCl<sub>4</sub> and a variety of thiocyanate salts (equation 22).<sup>176</sup> The Si-N bonds in (H<sub>3</sub>Si)<sub>3</sub>N are cleaved by HOCN and HSCN to give H<sub>3</sub>SiNCO and H<sub>3</sub>SiNCS, respectively, providing a route to these compounds that does not involve metal salts.<sup>177</sup>

Treatment of HSiCl<sub>3</sub> with silver or potassium salts also gives Si(NCE)<sub>4</sub> (E = O or S) together with the expected HSi(NCE)<sub>3</sub> species, which are prepared in greater yield from HSiI<sub>3</sub> and the silver salts.<sup>178</sup> As in the case of the perhalo compounds, the pseudohalides also undergo redistribution reactions (Scheme 30).<sup>179</sup>

**Scheme 30****Scheme 31**

The structures of the silyl species H<sub>3</sub>SiX (X = NCO, NCS, N<sub>3</sub>) have been examined in detail in electron diffraction and microwave spectroscopic studies. The microwave spectra of H<sub>3</sub>SiNCO and H<sub>3</sub>SiNCS suggest that the Si-N=C=O and Si-N=C=S linkages are linear, but electron diffraction studies show molecules that are bent at N. These data combined suggest that the ground state is linear but that the molecules are readily deformed, and in the gas phase at room temperature they spend most of their time bent.<sup>120</sup> In the solid state, the Si-N=C angle is 158° but this bent geometry appears to be due to weak but well-defined intermolecular Si···N interactions.<sup>120</sup> The structures of a range of silyl pseudohalides H<sub>3</sub>SiR (R = N<sub>3</sub>, NCO and NCS) have also been calculated, the results comparing well with those from experimental determinations (where these have been carried out) of the structures.<sup>180-182</sup> The linear (or near linear) arrangement in the silyl-isocyanate and -isothiocyanate has been attributed to p<sub>π</sub>-d<sub>π</sub> bonding involving the 3d orbitals of the silicon. The molecular structure of F<sub>3</sub>SiNCO (prepared by passing F<sub>3</sub>SiBr over AgOCN) in the gas phase also shows a bent Si-N=C angle of 160.7°. <sup>183</sup> The mixed halides/pseudohalides SiCl<sub>n</sub>(NCO)<sub>4-n</sub> (n = 1-3) (prepared by heating a mixture of SiCl<sub>4</sub> and Si(NCO)<sub>4</sub>) also have bent Si-N=C groups of 138, 136, and 145° for n = 3, 2, and 1, respectively.<sup>184</sup> The related disilyl species H<sub>3</sub>Si-N=C=N-SiH<sub>3</sub> has a near linear Si-N=C=N-Si linkage, rather than the cyanamide structure (H<sub>3</sub>Si)<sub>2</sub>NCN.<sup>185</sup>

Isocyanates and isothiocyanates both react with water in a manner similar to the halosilanes to give hydrated silica. They also react with primary and secondary amines to give silylamines which, on hydrolysis, afford *N*-mono- and *N,N*-disubstituted ureas and thioureas (Scheme 31), which is a useful synthesis of these compounds.<sup>186</sup>

#### 5.4.2 Silyl Cyanides and Isocyanides

The structure of H<sub>3</sub>SiCN (prepared from H<sub>3</sub>SiBr + AgCN) has been studied in detail. The gas-phase structure shows an

H–Si–C angle of 108.6° and in the solid phase 100.4° while the Si–C–N angle is linear and there are short intermolecular Si···N distances, indicating a donor–acceptor interaction which gives an almost linear chain formation that is not seen in the carbon analog, CH<sub>3</sub>CN.<sup>120,187</sup>

Although the OCN and SCN groups are normally iso when attached to silicon, the CN group is usually attached via the carbon. However, the reaction between F<sub>3</sub>SiBr or F<sub>3</sub>SiI and AgCN affords both F<sub>3</sub>SiCN and the silyl isocyanide F<sub>3</sub>SiNC.<sup>188</sup> The reaction of the sterically hindered chlorosilane (*t*-BuO)<sub>3</sub>SiCl with tetraethylammonium cyanide (equation 23) also affords a mixture of both the normal cyanide and the isocyanide, containing amounts of up to 6.5% of the latter. At 25 °C the equilibrium mixture contains 1.1% of the isocyanide isomer, apparently the only system that contains an appreciable amount of an isocyanide. The IR stretching frequencies for the C≡N and N≡C compounds are 2198 and 2103 cm<sup>−1</sup>, respectively.<sup>189</sup>

#### 5.4.3 Silyl Azides

The azide derivatives of silicon are generally more stable than organic azides although they may detonate on heating and should be handled with care. Silyl azides may be prepared by several routes (Scheme 32), the most important being hydrazoic acid cleavage of an Si–N bond and (in a manner similar to the other silyl pseudohalogens) by treatment of a silyl chloride with a metal azide.<sup>190</sup> In H<sub>3</sub>SiN<sub>3</sub> the Si–N–N angle is about 127°.<sup>191,192</sup>

### 5.5 Silicon–oxygen Compounds

Although a significant fraction of the Earth's crust comprises material containing SiO<sub>4</sub> structural units arranged in three-dimensional arrays, the uses of discrete monomeric Si(OR)<sub>4</sub> species have only been widely studied since about the 1950s. Along with the chlorosilanes, the alkoxy silanes and siloxanes are very useful and widely available compounds that are produced in large quantities.

#### 5.5.1 Silanols and Siloxanes and Their Sulfur, Selenium, and Tellurium Analogs

The propensity of silicon and oxygen to form materials in which the Si and O atoms alternate to form a polymer causes

Scheme 32

practical problems when preparations of small molecules containing the SiOH group are undertaken. Thus H<sub>3</sub>SiOH, H<sub>2</sub>Si(OH)<sub>2</sub>, HSi(OH)<sub>3</sub>, and H<sub>3</sub>SiSiH<sub>2</sub>OH have not been isolated in a pure form. The products obtained in attempted preparations of such species are invariably siloxanes owing to the condensation reaction that takes place very readily between two or more silanol molecules (Scheme 33). Hydrolysis of an SiCl<sub>3</sub> group attached to a transition metal may however lead to a stable Si(OH)<sub>3</sub> group (see Section 7 concerning transition metal complexes); also a wide variety of organosilanols R<sub>n</sub>Si(OH)<sub>4−n</sub> (*n* = 1–3; R = alkyl or aryl) are known where the steric effect of the R groups tends to hinder condensation reactions.<sup>193</sup>

The use of large, nitrogen-centered substituents at a silanetriol center does allow the isolation and characterization of stable silanetriols as shown in equation (24). These compounds can be used to prepare transition metal siloxide complexes (Scheme 34), still containing potentially moisture-sensitive Si–N bonds that may be precursors to metal-containing ceramics; for reviews of these compounds, see References 193–195.

The wide range of silicon compounds that are readily hydrolyzed means that the siloxane H<sub>3</sub>SiOSiH<sub>3</sub> is formed (probably via H<sub>3</sub>SiOH) in numerous reactions (Scheme 35).<sup>196</sup>

Similarly, hydrolysis of halodisilanes tends to give siloxane rather than silanol products (Scheme 36).<sup>196</sup>

The compounds (HSiO<sub>1.5</sub>)<sub>*n*</sub> with *n* = 4–7 may, however, be isolated from the careful hydrolysis of Cl<sub>3</sub>SiH. Figure 4 shows their polyhedral nature, which also suggests their other name of ‘sphaerosiloxanes’.<sup>121,197</sup> The octasiloxane (HSiO<sub>1.5</sub>)<sub>8</sub> may be fully chlorinated to give (ClSiO<sub>1.5</sub>)<sub>8</sub>, from which the methoxy derivative (MeOSiO<sub>1.5</sub>)<sub>8</sub> may be prepared by

Scheme 33

Scheme 34

Scheme 35

Scheme 36

treatment with  $\text{MeONO}$ .<sup>198</sup> For the case of  $n = 14$  two isomers, one of  $D_{3h}$  and one of  $C_{2v}$  symmetry, have been structurally characterized (Figure 5).<sup>199</sup> Larger silicates are treated elsewhere; reviews of the chemistry, preparation, and structures of the oligosilsesquioxanes are available.<sup>200–202</sup>

Figure 4  $D_{5h}$  isomer of  $(\text{HSiO}_{1.5})_n$  for  $n = 5$ 

The reactions of  $(\text{H}_3\text{Si})_2\text{O}$  fall into two general classes: those that proceed with Si–O bond cleavage, usually promoted by Lewis acids, and those that lead to condensation reactions, usually promoted by Lewis bases. Typical reactions are shown in Scheme 37.<sup>196</sup>

The preparation of the perchlorosiloxanes  $\text{Cl}_3\text{Si}(\text{OSiCl}_2)_n\text{SiCl}_3$  ( $n = 0\text{--}5$ ) has been discussed above in the halosilanes section. The highly reactive  $\text{Cl}_3\text{SiOH}$  may, however, be generated by photochemical oxidation of  $\text{SiHCl}_3$  by  $\text{O}_2$  or  $\text{O}_3$  at low temperature in either an argon matrix or

Scheme 37

Figure 5 Structures of large spherosiloxanes

in  $\text{SiCl}_4$ . The compound cannot be isolated but is stable in dilute solution for several days.<sup>203,204</sup> Hydrolysis of  $\text{H}_3\text{SiBr}$  affords  $\text{H}_3\text{SiOSiH}_3$ , while reaction between  $\text{H}_3\text{SiI}$  and  $\text{HgS}$ ,  $\text{Li}[\text{Al}(\text{SeH})_4]$  or  $\text{Ag}_2\text{Se}$ , and  $\text{Li}_2\text{Te}$  affords  $(\text{H}_3\text{Si})_2\text{E}$  ( $\text{E} = \text{S}, \text{Se}, \text{and Te}$ ), respectively.<sup>205–207</sup> The lower disilyl chalcogenides hydrolyze to give  $(\text{H}_3\text{Si})_2\text{O}$  as shown, for example, in equation (25).<sup>208</sup>

The reaction between  $\text{Cl}_3\text{SiH}$  or  $\text{Cl}_2\text{SiH}_2$  and sulfur affords thiols such as  $\text{Cl}_3\text{SiSH}$ .<sup>209,210</sup> Disilyl sulfide undergoes a variety of reactions as shown in Scheme 38.<sup>196</sup>

The Si–O–Si angle in  $(\text{H}_3\text{Si})_2\text{O}$  in the solid phase is unusually wide at  $144.1^\circ$  ( $144^\circ$  in the gas phase) for an  $\text{sp}^2$  hybridized atom, but this is similar to other siloxanes, and again has been proposed to reflect  $\text{p}_\pi\text{--d}_\pi$  bonding between Si and O.<sup>196</sup> As in the simple silyl halides, there are close nonbonded intermolecular interactions in the siloxane with an  $\text{Si}\cdots\text{O}$  distance of  $3.05\text{ \AA}$  and an O–Si–O angle close to  $180^\circ$ , giving a chain structure.<sup>120</sup> The bond shortening and wide Si–O–Si angles in siloxanes have been attributed to  $\text{p}_\pi\text{--d}_\pi$  interaction but molecular orbital calculations have suggested that these structural features are, in fact, the product of the unusually high ionic character of the Si–O bond, and that  $\text{p}_\pi\text{--d}_\pi$  bonding is of relatively little importance.<sup>211</sup> A useful discussion of the contributions of the bonding possibilities ( $\text{p}_\pi\text{--d}_\pi$ , Si–C  $\sigma^*$  interactions with Si–X bonds, and ionic factors) proposed for Si–X bonds ( $\text{X} = \text{electronegative element}$ ) can be found in Reference 212. The solid-state structures of  $(\text{H}_3\text{Si})_2\text{S}$  and  $(\text{H}_3\text{Si})_2\text{Se}$  show angles at the chalcogen of  $98.4$  and  $95.7^\circ$ , respectively. As

Scheme 38

for the oxygen analog, there are distinct though weaker intermolecular Si...S (or Se) interactions. However, in the siloxane case only, one silicon from each molecule is involved in intermolecular interactions, while in the S and Se analogs, both silicons show nonbonded interactions with the chalcogen giving all silicons five-coordination and the S and Se atoms tetrahedral coordination.<sup>213</sup>

The reaction of (H<sub>3</sub>Si)<sub>2</sub>O with BX<sub>3</sub> (X = F or Cl) affords H<sub>3</sub>SiOBX<sub>2</sub>. These compounds together with other X<sub>3</sub>SiOBX<sub>2</sub> species (X = H, F, or Cl) have had their structures calculated by MNDO methods. The compounds split into two types, one in which the Si–O–B angle is in the range from 140 to 152° (for X<sub>3</sub>SiOBH<sub>2</sub> (X = H, F or Cl) and H<sub>3</sub>SiOBF<sub>2</sub>) and the second in which the Si–O–B angle is 180° (X<sub>3</sub>SiOBCl<sub>2</sub> (X = H, F or Cl) and F<sub>3</sub>SiOBF<sub>2</sub>).<sup>214</sup>

Silanethiols are much more stable towards condensation reactions than their oxygen counterparts and may be isolated from insertion reactions of Si–H containing compounds with S at high temperature or by high-temperature reactions with H<sub>2</sub>S (Scheme 39).<sup>209,210</sup>

The disilyl chalcogenides (H<sub>3</sub>Si)<sub>2</sub>E (E = S, Se, Te) may be prepared from Li<sub>2</sub>E and H<sub>3</sub>SiBr. In the presence of H<sub>2</sub>E an equilibrium is set up with H<sub>3</sub>SiEH species (Scheme 40).<sup>215</sup>

Scheme 39

Scheme 40

Figure 6 Structures of siloxene materials

### 5.5.2 Siloxene

Siloxene is the name given to several materials that are prepared by the action of aqueous hydrochloric acid on calcium silicide, CaSi<sub>2</sub>. Two main types of siloxene are available, the so-called ‘Wohler’ and ‘Kautsky’ materials named after the chemists who carried out the original preparations. The siloxenes are prepared as shown in equations (26) and (27), and the structures, that have been the subject of much discussion, are now thought to be as shown in Figure 6. The preparations are carried out in the dark and under argon as the siloxenes are both photosensitive and can be oxidized, the Wohler material being a bright yellow, layered material and the Kautsky material being grayish-green. The effects of the reaction conditions on rate of formation of siloxene have been investigated in detail.<sup>216</sup> The recent interest in siloxene has arisen because it exhibits a strong yellow-green photoluminescence, unlike crystalline silicon which does not emit visible light because of its small indirect bandgap. The presence of siloxene contamination in porous silicon has also been suggested to account for the strong visible photoluminescence from porous silicon. A large number of studies on the electronic and optical properties of siloxene have been published; see References 217–220 and references therein.

### 5.5.3 Silicon Chalcogenides: SiS<sub>2</sub>, SiSe<sub>2</sub>, and SiTe<sub>2</sub>

The disulfide, SiS<sub>2</sub>, and the diselenide and ditelluride, SiSe<sub>2</sub> and SiTe<sub>2</sub>, are isostructural in the crystalline phase and have the form of chains of edge-sharing distorted SiS<sub>4</sub> or SiSe<sub>4</sub> tetrahedra with Si–S and Si–Se bond lengths of 2.133 and 2.275 Å, respectively.<sup>221</sup> The structure of glassy SiSe<sub>2</sub> has been investigated by solid-state <sup>29</sup>Si NMR spectroscopy, which suggests that three Si environments are present (analogous to SiS<sub>2</sub>) that differ in the number of edge-sharing tetrahedra involving each Si; these are shown in Figure 7.<sup>222–224</sup> Unlike SiO<sub>2</sub>, SiS<sub>2</sub>, SiSe<sub>2</sub>, and SiTe<sub>2</sub> hydrolyze rapidly in air.<sup>111</sup>

Figure 7 Silicon environments in glassy  $\text{SiSe}_2$

#### 5.5.4 Silyl Alkoxides, Phenoxides, and Their Sulfur Analogs

Simple  $(\text{RO})_4\text{Si}$  compounds may readily be prepared by the reaction between a chlorosilane and an alcohol (or phenol) (Scheme 41). A problem in this type of reaction is that the  $\text{HCl}$  formed may cause unwanted side reactions. This may be minimized by blowing dry  $\text{N}_2$  gas through the reaction mixture or heating the reaction so that  $\text{HCl}$  is driven off as it is formed, or a tertiary amine such as pyridine may be added to the reaction, which forms an amine hydrochloride salt that precipitates to remove the  $\text{HCl}$ .<sup>225</sup> Silicon alkoxides may also be made by reaction of a silicon halide and an alkali metal alkoxide (Scheme 41).<sup>226</sup>

The reaction between  $\text{Pb}(\text{SR})_2$  ( $\text{R} = \text{Me}, \text{Et}, \text{or Ph}$ ) and  $\text{SiCl}_4$  affords  $\text{Si}(\text{SR})_4$ . If a deficiency of lead salt is used, partially substituted species such as  $\text{Cl}_n\text{Si}(\text{SEt})_{4-n}$  ( $n = 1-3$ ) may be obtained which may subsequently be reduced by  $\text{LiAlH}_4$  to give  $\text{H}_n\text{Si}(\text{SEt})_{4-n}$  compounds.<sup>227</sup>

A further method for the preparation of alkyl silicates involves using mineral silicates that contain discrete silicate anions such as  $\text{SiO}_4^{4-}$  in  $\gamma\text{-Ca}_2\text{SiO}_4$  or  $\text{Si}_2\text{O}_7^{6-}$  in  $\text{Ca}_2\text{ZnSi}_2\text{O}_7$  (hardystonite) rather than polymeric silicate networks. The anions are protonated and then treated with alcohol to form alkoxysilanes (Scheme 42). This method removes the energy intensive formation of elemental  $\text{Si}$  (see Section 2) but unfortunately does not give particularly good yields. Alkoxysilanes  $(\text{RO})_3\text{SiH}$  and  $(\text{RO})_4\text{Si}$  ( $\text{R} = \text{Me}, \text{Et}, n\text{-Pr}$ ) are also formed in low yield from the direct reaction between  $\text{Si}/\text{Cu}$  alloy and  $\text{ROH}$  at  $260\text{--}300^\circ\text{C}$ .<sup>228</sup>

An unfortunate side reaction in the conversion of  $\text{SiCl}_4$  to  $\text{Si}(\text{OR})_4$  is that between the liberated  $\text{HCl}$  and the alcohol

Scheme 42

to give an alkyl chloride. This is particularly pronounced in the case of  $\text{MeOH}$  and higher alcohols such as isopropyl and butyl. (It should be noted that methoxysilanes such as  $\text{Si}(\text{OMe})_4$  are eye irritants and should be handled with care.) A more convenient route to such alkoxysilanes is via transesterification using  $(\text{EtO})_4\text{Si}$  (equation 28).

The preparation of mixed alkoxysilanes may be achieved by, for example, treating  $\text{SiCl}_4$  with two equivalents of  $\text{EtOH}$  to give  $(\text{EtO})_2\text{SiCl}_2$  and then with a second alcohol to give  $(\text{EtO})_2\text{Si}(\text{OR})_2$ . Aryl oxides do not suffer so readily from the reaction between  $\text{ArOH}$  and  $\text{HCl}$  and may easily be prepared from  $\text{SiCl}_4$  and an appropriate phenol. The simplest phenoxysilane,  $(\text{PhO})_4\text{Si}$ , is remarkable in that it may be distilled in air at over  $400^\circ\text{C}$ . Careful hydrolysis of  $\text{Si}(\text{OR})_4$  affords silicate anions such as  $\text{Si}_2\text{O}_7^{6-}$ , and  $\text{Si}_3\text{O}_{10}^{8-}$ , and so on, or they may be formed during the reaction of an alcohol with  $\text{SiCl}_4$  owing to the presence of some water. By analogy with  $\text{SiCl}_4$ , the reaction between  $(\text{Cl}_3\text{Si})_2\text{O}$ ,  $\text{Cl}_3\text{SiO}(\text{SiCl}_2)\text{OSiCl}_3$ , or  $\text{Cl}_3\text{SiSiCl}_3$  with anhydrous alcohol gives  $[(\text{RO})_3\text{Si}]_2\text{O}$ ,  $(\text{RO})_3\text{SiO}[\text{Si}(\text{OR})_2]\text{OSi}(\text{OR})_3$ , and  $(\text{RO})_3\text{SiSi}(\text{OR})_3$ , respectively.

The hydrolysis of  $(\text{EtO})_4\text{Si}$  (and the subsequent polycondensation of  $\text{Si-OH}$  containing molecules) has been the subject of considerable investigation because of its importance in the fabrication of glasses and colloidal silica via the sol-gel process (see *Sol-Gel Synthesis of Solids*). Hydrolysis of the  $\text{Si-O}$  bond in alkoxysilanes is also very widely used to attach silicon compounds to surfaces and in coupling reactions.<sup>229,230</sup> The fundamental reaction types involved in the formation of polymeric silica materials (via, for example, cyclic oligomers similar to those shown in Figures 4 and 5) from monomeric  $(\text{RO})_4\text{Si}$  compounds are shown in Scheme 43.

Scheme 41

Scheme 43

The reaction rates, the importance of various intermediates, and the properties of the end product of hydrolysis are highly dependent on the presence of catalysts (e.g., mineral acids or ammonia), the steric and inductive effects of the R groups, the water:alkoxysilane ratio, and the solvent. These factors together with a mechanistic analysis of the reaction have been discussed in detail.<sup>231–234</sup> In recent years, the hydrolysis of a wide range of compounds of the general form  $\text{RSiOR}^1_3$  (where R = an organic group and  $\text{R}^1 = \text{Me}$  or  $\text{Et}$ ) has been used to prepare organically modified silicas (ORMOSILs) which have a variety of interesting properties.<sup>235</sup>

Alkoxysilanes react with organometallic reagents such as Grignard reagents and organolithium compounds to give organosilicon compounds (see *Silicon: Organosilicon Chemistry*) (Scheme 44) in a manner similar to the halosilanes. These reactions are, however, slower and less vigorous and are useful starting materials in the production of organosilanes.

Alkoxysilanes may be converted back to chlorosilanes by treatment with, for example,  $\text{PCl}_5$  or  $\text{AlCl}_3$ , and they react with carboxylic acids  $\text{RCO}_2\text{H}$  to give esters  $(\text{RCO}_2)_4\text{Si}$ . Disilyl sulfide,  $(\text{H}_3\text{Si})_2\text{S}$ , reacts with  $\text{MeOH}$  or  $\text{PhOH}$  to give  $\text{MeOSiH}_3$  and  $\text{PhOSiH}_3$ , respectively.<sup>236,237</sup> The  $\text{Si}-\text{O}-\text{C}$  angles are  $120.6(9)^\circ$  and  $121(1)^\circ$ , respectively, somewhat lower than in disilyl ether. The structure of  $\text{MeOSiF}_3$  prepared by the route shown in equation (29) has also been investigated and has an  $\text{Si}-\text{O}-\text{C}$  angle of about  $132^\circ$ .<sup>238</sup>

The structures of these compounds and related materials have been discussed.<sup>239</sup> The structure of  $(\text{MeO})_4\text{Si}$  is of  $S_4$  symmetry with an  $\text{Si}-\text{O}-\text{C}$  angle of  $122.3^\circ$ . As in  $\text{MeOSiF}_3$ , the  $\text{Si}-\text{O}$  bond length is shorter than normal owing to several electronegative substituents being present.<sup>240</sup>

Scheme 44

### 5.5.5 Silyl Esters and Thioesters

Silyl esters may be formed using a variety of preparative routes as shown in Scheme 45.

Compounds containing both alkoxy and ester groups,  $(\text{RO})_n\text{Si}[(\text{CO}(\text{O})\text{R})]_{4-n}$ , may be made by redistribution reactions involving  $\text{Si}(\text{OR})_4$  and  $(\text{RCO})_2\text{O}$ . Alkoxysilanes,  $(\text{RO})_4\text{Si}$ , may also be prepared by passing dimethyl or diethyl carbonate over  $\text{SiO}_2/\text{KOH}$  at  $500\text{--}600\text{ K}$ .<sup>241</sup> Silyl esters,  $\text{H}_3\text{SiO}(\text{C}=\text{O})\text{R}$ , may also be prepared in the gas phase by reaction between  $(\text{H}_3\text{Si})_3\text{N}$  and  $\text{RCO}_2\text{H}$  or by reaction of  $\text{H}_3\text{SiBr}$  with  $n\text{-Bu}_3\text{SnO}(\text{C}=\text{O})\text{R}$  ( $\text{R} = \text{H}, \text{Me}, \text{CF}_3$  etc.). The thioacetate  $\text{H}_3\text{SiO}(\text{C}=\text{S})\text{Me}$  has also been prepared by the butyltin method.<sup>242</sup> Short intermolecular distances are also found in  $\text{H}_3\text{SiO}(\text{C}=\text{E})\text{Me}$  ( $\text{E} = \text{O}$  or  $\text{S}$ ), where zig-zag chains are formed in the solid state via  $\text{Si} \cdots (\text{E}=\text{C})$  interactions. The  $\text{H}_3\text{Si}$  group is *cis* to the carbonyl oxygen in both the solid and vapor phase.<sup>120</sup>

Silicon tetraacetate may be prepared by the reaction between  $\text{SiCl}_4$  and acetic anhydride<sup>243</sup> and has a structure comprising discrete molecules with no bridging by acetate, although there is one short intramolecular distance between a carbonyl oxygen and the silicon in each molecule.<sup>244,245</sup> Silyl esters,  $\text{H}_3\text{SiOC}(\text{O})\text{R}$  ( $\text{R} = \text{H}, \text{Me}, \text{CF}_3$ , etc.), and the thioacetate  $\text{H}_3\text{SiOC}(\text{S})\text{Me}$  may be prepared by either gas-phase reaction of  $(\text{H}_3\text{Si})_3\text{N}$  with organic acids or from  $\text{H}_3\text{SiBr}$  and tributyltin acetate, equation (30).<sup>242,246</sup> Treatment of  $\text{LiSeSiH}_3$  with  $\text{MeC}(\text{O})\text{Cl}$  affords the analogous selenoacetate  $\text{H}_3\text{SiOC}(\text{Se})\text{Me}$ , which is in equilibrium with its isomer  $\text{H}_3\text{SiSeC}(\text{O})\text{Me}$ <sup>247</sup> while the difunctional  $\text{H}_2\text{Si}(\text{OCOH})_2$  may be prepared from  $\text{H}_2\text{SiBr}_2$  and  $\text{Bu}_3\text{SnOCOH}$ .<sup>248</sup>

The structures of  $\text{H}_3\text{SiOCOH}$  and  $\text{H}_2\text{Si}(\text{OCOH})_2$  have been determined in the gas phase.<sup>242,249</sup> In the monoformate the  $\text{Si}-\text{O}-\text{C}$  angle is  $116.8^\circ$  and the  $\text{H}_3\text{Si}$  group is twisted

Scheme 45

away from a planar cis arrangement by  $21^\circ$ . The diformate has an Si-O-C angle of  $120.4^\circ$  with one formate group in a cis and one in a trans arrangement about the Si-O bond, as shown in (8).

The reaction between catechol and Si/Cu alloy at high temperature and pressure affords the spiro compound (9) as a glassy white material.<sup>250</sup> The structure of (9) has been the subject of some dispute. Although it was originally thought to have a planar geometry at silicon this has not been confirmed, and it is likely that it has a normal tetrahedral arrangement as found in the related (10) and (11).<sup>251,252</sup>

Compound (10) and the related spirocyclic compounds such as (12) and (13) may be conveniently prepared from the reaction between  $(\text{EtO})_4\text{Si}$  and a 1,2-, 1,3-, or 1,4-diol in the presence of a catalytic amount of metal alkoxide such as NaOMe or  $(i\text{-PrO})_4\text{Ti}$ .<sup>253</sup>

Tris(thioalkyl)silanes may be prepared by reaction between  $\text{Cl}_3\text{SiH}$  and thiols in a manner similar to the preparation of alkoxysilanes and are useful reagents for radical reductions of alkyl halides or alkenes in organic chemistry (Scheme 46).<sup>254</sup>

The reactions between  $(\text{H}_3\text{Si})_2\text{E}$  ( $\text{E} = \text{S}$  or  $\text{Se}$ ) and  $\text{H}_2\text{SiCl}_2$  or  $\text{HSiCl}_3$  (Scheme 47) afford an interesting series of compounds containing several Si to chalcogen bonds such as  $(\text{HSi})_4\text{S}_6$  (14), which was found to have an adamantane-type structure.<sup>255</sup>

The reaction between  $(\text{CH}_2\text{SNa})_2$  and  $\text{SiCl}_4$  gives the spirocyclic (15), which has a distorted tetrahedral arrangement

Scheme 46

Scheme 47

at silicon with the S–Si–S angles being in the range 100.1–124.7°. <sup>256</sup> The reaction of *t*-BuOH and SiS<sub>2</sub> gives a mixture of (*t*-BuO)<sub>2</sub>Si(SH)<sub>2</sub>, (*t*-BuO)<sub>3</sub>SiSH, and (16) which, although planar, does not have a square Si<sub>2</sub>S<sub>2</sub> ring but has endocyclic angles at Si and S of 97.8 and 82.2°, respectively. <sup>257</sup>

The (*t*-BuO)<sub>3</sub>SiS group has been used as a ligand on various metals. <sup>258</sup> The bulky thiolate group is introduced by reaction of the thiol (*t*-BuO)<sub>3</sub>SiSH with a suitable metal salt such as a nitrate or an oxide. The silver derivative is a cyclic tetramer, [(*t*-BuO)<sub>3</sub>SiS]<sub>4</sub>Ag, while the thallium and lead derivatives form planar and nonplanar cyclic dimers, [(*t*-BuO)<sub>3</sub>SiSM]<sub>2</sub>, respectively. <sup>239</sup> The reaction between (*t*-BuO)<sub>3</sub>SiNa and (*t*-BuO)<sub>3</sub>SiCl gives [(*t*-BuO)<sub>3</sub>Si]<sub>2</sub>E (E = O or S), both of which are bent at the E atom. <sup>259</sup> By contrast, the Si–O–Si angle in the related peroxide, [(*t*-BuOO)<sub>3</sub>Si]<sub>2</sub>O, is 180°. <sup>260</sup>

## 5.6 Silicon–Nitrogen Compounds

The structures of simple silylamines have been the subject of much discussion and investigation. This has been due in large part to the finding that (H<sub>3</sub>Si)<sub>3</sub>N is, unlike its pyramidal (H<sub>3</sub>C)<sub>3</sub>N analog, planar at nitrogen. The silicon compound is also a much weaker Lewis base than the carbon analog and this has been attributed to p<sub>π</sub>–d<sub>π</sub> bonding between the lone pair of electrons on the nitrogen and the vacant d-orbitals on silicon but ionic contributions and Si–C σ\* interactions with the Si–N bond are probably also important (see Reference 212). Such bonding would increase the Si–N–Si angles to 120° and reduce the donor properties of the lone pair. The chemistry and physical properties of Si–N compounds (excluding Si<sub>3</sub>N<sub>4</sub>) have been discussed in detail. <sup>261,262</sup>

### 5.6.1 Preparations of Compounds Containing Si–N Bonds

The reaction between ammonia and H<sub>3</sub>SiCl or H<sub>3</sub>SiBr affords (H<sub>3</sub>Si)<sub>3</sub>N as a low-boiling colorless liquid (equation 31). <sup>196,263</sup> Disilylamine, (H<sub>3</sub>Si)<sub>2</sub>NH, which is also planar at nitrogen, is unstable as a liquid and disproportionates to give trisilylamine and ammonia, but it may be made by reaction of Ph<sub>2</sub>NSiH<sub>3</sub> and ammonia in a transamination reaction. <sup>135</sup> Similarly, H<sub>3</sub>SiNH<sub>2</sub> also disproportionates, but it can be prepared at low pressure in the gas phase from the reaction between H<sub>3</sub>SiI and ammonia. <sup>264</sup>

The reaction between halosilanes and ammonia or primary or secondary amines is the most widely used synthetic route to compounds containing Si–N bonds. Such reactions are greatly controlled by steric effects: if large groups are present on either the silicon or the amine, then less than full substitution may occur. For example, ammonia reacts with chlorosilanes to give a variety of products depending on the size of the chlorosilane (equation 32).

This is also the case for the reaction of polyhalosilanes with amines, where small groups on the nitrogen allow a higher degree of substitution to be achieved (Scheme 48).

This type of reaction is usually carried out using chlorosilanes because of their ready availability, but bromo- or iodosilanes are more reactive and may give better yields. Reactions of fluorosilanes with amines tend to give, because of the relatively high Lewis acidity of fluorosilanes, stable donor–acceptor adducts such as SiF<sub>4</sub>·HNR<sub>2</sub>. Heating such adducts, however, does give F<sub>3</sub>SiNR<sub>2</sub> (R = Me, Pr, Bu) species in good yield. A successful method to overcome the steric problems encountered above is to use an alkali metal or magnesium amide to carry out a metathesis reaction. For example, although the tetraamidodisilane Si(NHBu-*t*)<sub>4</sub> is not available by the silyl chloride plus amine route (see Scheme 48), it may be obtained using a magnesium amide (equation 33). Here again the use of the more reactive halogens allows successful substitution by the bulky groups. For a more detailed discussion of this type of reaction, and Si–N compounds in general, see Lappert *et al.* <sup>262</sup>

Tetraaminosilanes may be prepared by several methods using either a secondary amine or a metal amide (Scheme 49). <sup>265</sup> Mixed amides may also be prepared.

The reaction between Me<sub>2</sub>NH and H<sub>3</sub>SiBr gives Me<sub>2</sub>NSiH<sub>3</sub>, which has an unusually high melting point of 276 K, about 120 K higher than the closely related compounds NMe<sub>3–x</sub>(SiH<sub>3</sub>)<sub>x</sub> (x = 0–3). The surprising properties of Me<sub>2</sub>NSiH<sub>3</sub> are associated with its unusual structure, which is pentameric with N atoms at the corners of a pentagon and SiH<sub>3</sub> groups midway along the pentagon sides (Figure 8). <sup>120</sup>

Scheme 48

Scheme 49

Figure 8 The pentameric structure of  $\text{Me}_2\text{NSiH}_3$ 

The nitrogen atoms also have a pyramidal geometry rather than the planar  $(\text{H}_3\text{Si})_3\text{N}$ , and the N–Si–N angles are about  $177^\circ$ .

The controlled reaction of two equivalents of ammonia with one of  $\text{SiCl}_4$  gives a mixture of monomeric, oligomeric, and polymeric products which may undergo further reactions typical of Si–N compounds (Scheme 50).<sup>266</sup>

Scheme 50

Scheme 51

The reaction between  $\text{H}_3\text{SiBr}$  and  $\text{F}_2\text{PNH}_2$  in the vapor phase at room temperature gives  $\text{H}_3\text{SiNHPF}_2$ , which can be isolated and which reacts with a further equivalent of  $\text{H}_3\text{SiBr}$  to give  $(\text{H}_3\text{Si})_2\text{NPF}_2$ .<sup>267,268</sup> The diphosphino compound  $\text{H}_3\text{SiN}(\text{PF}_2)_2$  can be prepared in a similar manner (Scheme 51).<sup>268</sup> All three of the compounds are planar at nitrogen.<sup>267,269</sup>

The hexachloro monomer  $(\text{Cl}_3\text{Si})_2\text{NH}$  may react via  $\text{SiCl}_3$ ,  $\text{Cl}$ , or  $\text{H}$  substitution reactions.<sup>270</sup> Heating the lithium compound (17) gives the cyclic dimer, presumably via elimination of  $\text{LiCl}$  and dimerization of the reactive intermediate  $\text{Cl}_2\text{Si}=\text{NSiCl}_3$  (Scheme 52).

The cyclic trimer (18), formed by condensation reactions in a manner similar to cyclic siloxanes from  $\text{SiOH}$  compounds, has a planar  $\text{Si}_3\text{N}_3$  skeleton with Si–N–Si and N–Si–N angles of  $131$  and  $109^\circ$ , respectively.<sup>271</sup>

### 5.6.2 Structures of Silyl Amines

Structural data for several silyl amines are given in Table 7. Detailed discussions are given in appropriate places throughout this section.

### 5.6.3 Reactions of Silyl Amines

Silyl amines usually react readily with water or alcohols to give compounds containing Si–OR groups ( $\text{R} = \text{H, Me, Et, etc.}$ ) and with  $\text{HCl}$  to give a chlorosilane. The poor donor properties of  $(\text{H}_3\text{Si})_3\text{N}$  mean that it does not form adducts as readily as  $\text{Me}_3\text{N}$ , no adduct is formed with  $\text{Me}_3\text{B}$ , and only weak adducts are formed with  $\text{BF}_3$  or  $\text{BCl}_3$ . Reactions of  $(\text{H}_3\text{Si})_3\text{N}$  are summarized in Scheme 53.<sup>196</sup>

### 5.6.4 Silicon Nitride, $\text{Si}_3\text{N}_4$

Silicon forms the widely studied nitride  $\text{Si}_3\text{N}_4$  when heated at high temperature ( $>1400^\circ\text{C}$ ) in a nitrogen

Scheme 52

**Table 7** Structural details of several silylamines<sup>112</sup>

| Compound                                                                           | Structure                                  | N–Si (Å) | Method <sup>a</sup> | Si–N–P, Si–N–Si, or Si–N–C angle (°) |

Scheme 53

microelectronics industry and in the fabrication of solar cells has been discussed in detail.<sup>274</sup> Two main forms of Si<sub>3</sub>N<sub>4</sub> are known, called  $\alpha$  and  $\beta$ . Both structures are similar, comprising Si<sub>4</sub>N tetrahedra, the difference being in how they are arranged in the crystal lattice. Interestingly, the NSi<sub>3</sub> groups within the structure are nearly planar, that is, similar to the arrangement found in (H<sub>3</sub>Si)<sub>3</sub>N.<sup>275</sup> Silicon nitride may be prepared in several ways, for example, Scheme 54.

### 5.7 Silicon, Phosphorus, Arsenic, and Antimony Compounds

atmosphere. Interest in this ceramic material is due to its good refractory properties. The use of silicon nitride in the

Monosilyl compounds (H<sub>3</sub>SiMH<sub>2</sub>) of phosphorus and arsenic are known and they may be prepared in a variety of

Scheme 54

Scheme 55

ways (Scheme 55); similar preparative routes are successful in the preparation of  $(\text{H}_3\text{Si})_2\text{EH}$ ,  $(\text{H}_3\text{Si})_3\text{E}$ , and  $\text{H}_3\text{SiSiH}_2\text{EH}_2$  ( $\text{E} = \text{P}$  or  $\text{As}$ ).<sup>196</sup>

The mercury sensitized photolysis of a mixture of  $\text{F}_3\text{SiSiF}_3$  and  $\text{PF}_3$  affords  $\text{P}(\text{SiF}_3)_3$  as a colorless air-sensitive liquid. It reacts with a deficiency of water to give  $(\text{F}_3\text{Si})_2\text{PH}$  and  $\text{F}_3\text{SiPH}_2$  and with bromine to give  $\text{PBr}_5$  and  $\text{F}_3\text{SiBr}$ .<sup>276</sup>

There are many cyclic compounds known containing P and Si atoms in the ring but the majority have organic substituents on the silicon. (Details of the structures of such compounds are available.<sup>112</sup>) An exception is the spirocyclic compound (**19**), formed using an alkali metal-phosphorus derivative (equation 34).<sup>277</sup>

The lithium phosphide  $\text{Li}_3\text{P}_7$  also reacts with silyl halides and with  $\text{H}_3\text{SiX}$  ( $\text{X} = \text{Br}$  or  $\text{I}$ ) to form the tricyclic species (**20**).<sup>278</sup>

### 5.7.1 Reactions of Silicon–Phosphorus, –Arsenic, and –Antimony Derivatives

The reaction between  $\text{SiH}_4$  and  $\text{PH}_3$  gives  $\text{H}_3\text{SiPH}_2$ , which may be alkylated via  $\text{H}_3\text{SiPLi}_2$  (Scheme 56).<sup>279</sup> Treatment of

Scheme 56

Scheme 57

Scheme 58

$\text{Si-H}$  containing silylphosphines, however, leads to cleavage of an  $\text{Si-P}$  bond and alkylation at silicon. These reactions, and many other interesting cyclic and acyclic phosphines, most of which contain alkyl groups on silicon, are discussed in more detail by Fritz.<sup>280</sup>

The silyl phosphorus and arsenic compounds react with a variety of reagents and form adducts more readily with Lewis acids than the silyl amines (Scheme 57).<sup>196</sup>

The reaction of  $\text{MeLi}$  with Group 15 (but not N) and Group 16 silyl compounds affords metal derivatives (Scheme 58).

When the spirocyclic compound (**19**) is heated, dimerization occurs to give an unusual dispirocyclic compound containing three-, four-, and five-membered rings containing silicon (equation 35).<sup>281</sup>

### 5.7.2 Structures of Silicon–Phosphorus, –Arsenic, and –Antimony Derivatives

Structural data for trisilyl compounds of the Group 15 elements are shown in Table 8. As would be expected, the

**Table 8** Structural data for trisilyl compounds<sup>196</sup>

| Compound                            | Si–H (Å) | Si–M (Å) | Si–M–Si (°) |
|-------------------------------------|----------|----------|-------------|
| (H <sub>3</sub> Si) <sub>3</sub> N  | 1.54     | 1.738    | 119.6       |
| (H <sub>3</sub> Si) <sub>3</sub> P  | 1.50     | 2.247    | 95          |
| (H <sub>3</sub> Si) <sub>3</sub> As | 1.48     | 2.352    | 91.5        |
| (H <sub>3</sub> Si) <sub>3</sub> Sb | 1.394    | 2.557    | 88.6        |

Si–M bond length increases on going down the group. Only the amine is planar at nitrogen; the structures of (H<sub>3</sub>Si)<sub>3</sub>E (E = P, As and Sb) show a steady decrease in Si–E–Si angle on going down the group,<sup>282</sup> any p<sub>π</sub>–d<sub>π</sub> interaction presumably being rather weaker on descending the group.<sup>196</sup> A more detailed discussion of these compounds is available.<sup>112</sup>

The structures of H<sub>3</sub>Si–E derivatives (E = Li, Be, B, N, O, C, P, S, Cl, etc.) have been the subject of many theoretical investigations. Despite the fact that H<sub>3</sub>SiNH<sub>2</sub> is unknown, it is calculated also to be planar at nitrogen.<sup>283</sup>

### 5.8 Compounds Containing Silicon to Boron Bonds

Compounds containing Si–B bonds are comparatively rare but the in situ coupling of SiCl<sub>4</sub> and (MeO)<sub>2</sub>BCl affords Si[B(OMe)<sub>2</sub>]<sub>4</sub> which undergoes transesterification without cleavage of the Si–B bonds (equation 36).<sup>284</sup> The reaction between F<sub>2</sub>Si: and BF<sub>3</sub> affords F<sub>3</sub>SiSiF<sub>2</sub>BF<sub>2</sub> and F<sub>3</sub>SiSiF<sub>2</sub>SiF<sub>2</sub>BF<sub>2</sub>.<sup>285</sup>

### 5.9 Compounds Containing Si–C and Si–Si Bonds

The vast majority of compounds containing Si–C bonds are dealt with in another article (*see Silicon: Organosilicon Chemistry*), although silyl cyanides are treated in Section 5.4.2 above. The perhydrosilanes such as H<sub>3</sub>Si(SiH<sub>2</sub>)<sub>n</sub>SiH<sub>3</sub> are covered in Section 5.1.

The photodecomposition of SiH<sub>4</sub>/GeH<sub>4</sub> mixtures affords H<sub>3</sub>SiSiH<sub>3</sub> and H<sub>3</sub>SiGeH<sub>3</sub> by insertion of the initially formed H<sub>2</sub>Si: into a Si–H or Ge–H bond of SiH<sub>4</sub> or GeH<sub>4</sub>, respectively.<sup>286</sup>

Treatment of SiCl<sub>4</sub> with LiSnMe<sub>3</sub> affords Si(SnMe<sub>3</sub>)<sub>4</sub>, which reacts with MeLi to give (21); the latter is useful for introducing the Si(SnMe<sub>3</sub>)<sub>3</sub> ligand (in an analogous fashion to the widely used Si(SiMe<sub>3</sub>)<sub>3</sub> ligand) into complexes such as (22) (Scheme 59). The Si–W distance in the tungsten complex is 2.652 Å.<sup>287</sup>

**Scheme 59**

Numerous Group 14 carborane complexes have been prepared, in which the main group metal interacts with a C<sub>2</sub>B<sub>3</sub> fragment in an η<sup>5</sup>-fashion. Such complexes are usually formed by reaction of an alkali metal carborane with a silicon chloride (equation 37). (For a more detailed discussion of this work see Hosmane and Maguire.<sup>288</sup>)

### 5.10 Silicon Carbide

The preparation, manufacture, and reactions of SiC have been discussed in detail in Gmelin,<sup>289</sup> as have the electrical, mechanical, and other properties of both crystalline and amorphous SiC.<sup>290</sup> Silicon carbide results from the pyrolysis of a wide range of materials containing both silicon and carbon but it is manufactured on a large scale by the reduction of quartz in the presence of an excess of carbon (in the form of anthracite or coke), (Scheme 60), and more recently by the pyrolysis of polysilanes or polycarbosilanes (for a review, see Reference 291). Although it has a simple empirical formula, silicon carbide exists in at least 70 different crystalline forms based on either the hexagonal wurtzite (ZnS) structure α-SiC, or the cubic diamond (zinc blende) structure β-SiC. The structures differ in the way that the layers of atoms are stacked, with Si being four-coordinate in all cases.

The industrial interest in SiC derives from its high mechanical and chemical stability as well as its hardness (9.5 on the Moh scale), which makes it a useful abrasive. When pure, α-SiC is an intrinsic semiconductor, but it may be doped

**Scheme 60**

with various impurities to give an extrinsic semiconductor.  $\beta$ -SiC is also used as a high-temperature semiconductor.

## 6 TRANSITION METAL SILYL COMPLEXES

The interest in transition metal silyl derivatives stems largely from an interest in how such compounds compare with the very extensive organometallic chemistry of the transition elements and also because of the industrial importance of the *Hydrosilation* reaction used for the preparation of organosilicon compounds (see **Silicon: Organosilicon Chemistry**). There is a variety of methods for preparing compounds containing transition metal to silicon bonds. The most common are oxidative addition of an Si–X bond (X is usually H) to a transition metal complex, the use of transition metal anions, and the use of silyl alkali metal derivatives (Scheme 61). There is a wide variety of compounds known and, as the principal focus of this article is silicon, they will be arranged according to the groups on silicon. Recent structural studies and developments in the chemistry of transition metal silyl compounds have been reviewed.<sup>292–298</sup>

### 6.1 Compounds Containing SiH<sub>3</sub> and Related Ligands

The Si–H bonds within a silane are generally more reactive toward *Oxidative Addition* than other Si–X bonds, for example, where X is halogen or SH. For example, the reactions between various H<sub>3</sub>SiX species (X = H, Cl, or SiH<sub>3</sub>) and *trans*-[PtH<sub>2</sub>{P(C<sub>6</sub>H<sub>11</sub>)<sub>3</sub>}<sub>2</sub>] afford compounds (**23**)

Scheme 61

in which reaction at the Si–H rather than the Si–X bonds have occurred (equation 38).<sup>299</sup> The X-ray structure of (**23**; X = H) gives Pt–Si 2.382 Å; Si–H stretching frequencies are 2025 and 2020 cm<sup>–1</sup>.

Disilyl chalcogen compounds react in a similar manner (equation 39), to give both mononuclear complexes and bridged complexes (if excess platinum hydride precursor is used).<sup>300</sup>

The silyl amines and phosphines also give similar complexes (Scheme 62).<sup>301</sup>

The salt elimination route is also a useful method, relying on the reaction between a silyl halide and a transition metal anion, for example, equation (40).<sup>302</sup> The IR spectra of such compounds are informative; values of 2141, 2136, and 2132 cm<sup>–1</sup> for the disilyl compound and 2142 cm<sup>–1</sup> for the silyl compound are found for the Si–H stretching frequencies.

In a similar manner, H<sub>3</sub>SiI and H<sub>2</sub>SiI<sub>2</sub> react with NaCo(CO)<sub>4</sub> to give silyl cobalt complexes (Scheme 63). The Si–Co bond in these complexes is cleaved by H–X species (X = F, Cl) and HgX<sub>2</sub> (X = Cl or I) to give H<sub>3</sub>SiX and either HCo(CO)<sub>4</sub> or Hg[Co(CO)<sub>4</sub>]<sub>2</sub>. The IR stretches for H<sub>3</sub>SiCo(CO)<sub>4</sub> are at 2164, 2160, and 2154 cm<sup>–1</sup>.<sup>303</sup> The reaction between H<sub>3</sub>SiI and NaMn(CO)<sub>5</sub> proceeds in a similar manner.

The metal–Si bond is inert towards HCl and HgX<sub>2</sub> (X = Cl or I) at room temperature. At higher temperatures, chlorosilyl derivatives are produced in the reaction with HCl (Scheme 64).<sup>304</sup> The thermal decomposition of the metal

Scheme 62

Scheme 63

Scheme 64

silyl complexes  $[\text{Co}(\text{CO})_4(\text{SiH}_3)]$ ,  $[\text{Fe}(\text{CO})_4(\text{SiH}_3)_2]$ , and  $[\text{Mn}(\text{CO})_5(\text{SiH}_3)]$  at  $500^\circ\text{C}$  gives the metal silicides  $\text{CoSi}$ ,  $\beta\text{-FeSi}_2$ , and  $\text{MnSi-Mn}_5\text{Si}_3$ , respectively.<sup>305</sup> In the presence of Lewis bases such as  $\text{Me}_3\text{N}$  and pyridine, 1:2 adducts  $(\text{H}_3\text{Si})(\text{B})_2\text{M}(\text{CO})_n$  ( $\text{M} = \text{Mn}$  or  $\text{Co}$ ,  $n = 5$  or  $4$ , respectively) are formed which are thought to have ionic structures of type  $(\text{H}_3\text{Si} \cdot 2\text{B})^+ [\text{M}(\text{CO})_n]^-$ .<sup>306</sup>

If more than one Si-H group is present in the silane, then photolysis may lead to bridging  $\text{H}_2\text{Si}$  groups, for example, the manganese complex (24), which has an Si-Mn distance of  $2.434 \text{ \AA}$  and an Mn-Si-Mn angle of  $124.4^\circ$ ; (Scheme 65).<sup>307</sup> The reaction between  $\text{H}_3\text{SiK}$  and  $\text{Cp}_2\text{TiCl}_2$  (Scheme 65) affords the olive-green bridged complex (25), presumably via the disilyl complex  $\text{Cp}_2\text{Ti}(\text{SiH}_3)_2$ .<sup>308</sup>

The molecular structures of  $\text{H}_3\text{SiMn}(\text{CO})_5$ ,  $\text{H}_3\text{SiRe}(\text{CO})_5$ , and  $\text{H}_3\text{SiCo}(\text{CO})_4$  have all been determined in the gas phase.<sup>309-311</sup> The Si-M bond distances are  $2.407$ ,  $2.562$ , and  $2.381 \text{ \AA}$  for the Mn, Re, and Co complexes, respectively.

Although it is difficult to estimate what might be expected for these distances, they all seem relatively short. This has been attributed to  $d \rightarrow \pi$ -bonding using the vacant d-orbitals on silicon. More detailed discussions of transition metal  $\text{SiH}_3$  complexes have been published.<sup>292-298</sup>

Silyl complexes also result from the reaction between a silyl anion and a metal halide, for example, in the formation of (26), which has an Si-H stretching frequency of  $2103 \text{ cm}^{-1}$  (equation 41).<sup>312</sup>

The search for transition metal complexes that can activate alkanes has led to investigations into the potential of metal complexes to coordinate silanes. In 1995, the first  $\text{SiH}_4$  complexes were prepared according to Scheme 66. These

Scheme 66

Scheme 65

complexes have been characterized by multinuclear NMR spectroscopy and X-ray crystallography which show the metal center to have a distorted octahedral geometry and the CO and SiH<sub>4</sub> ligands to be cis to each other. For the complex containing the (Et<sub>2</sub>PCH<sub>2</sub>)<sub>2</sub> ligand an equilibrium between the  $\eta^2$ -SiH<sub>4</sub> complex and a hydrosilyl, (27), complex is found.<sup>313</sup> More recently, complexes, (28), in which an SiH<sub>4</sub> ligand bridges between two metals have been prepared, equation (42).<sup>314</sup> A variety of complexes are now known in which an Si-H bond is bound to the metal in an  $\eta^2$ -fashion; many of these contain organic substituents at Si, and their chemistry has been reviewed.<sup>315-317</sup>

## 6.2 SiX<sub>3</sub> Containing Ligands (X = F or Cl)

Hexafluorodisilane breaks down in a radiofrequency glow-discharge to give trifluorosilyl radicals that react with a variety of metal atoms when co-condensed on a cold surface (equation 43). This method allows the synthesis of a range of homoleptic SiF<sub>3</sub> metal derivatives (*see Homoleptic Compound*).<sup>318</sup>

If other ligands are also co-condensed or are added to coordinatively unsaturated F<sub>3</sub>Si-M species, then further complexes may be prepared, for example, ( $\eta^6$ -toluene)Ni(SiF<sub>3</sub>)<sub>2</sub>, (F<sub>3</sub>Si)<sub>2</sub>Pd(PMe<sub>3</sub>)<sub>2</sub>, (F<sub>3</sub>Si)<sub>2</sub>Cd-glyme, and (F<sub>3</sub>Si)<sub>2</sub>Zn·2(pyridine). The bis F<sub>3</sub>Si complex (F<sub>3</sub>Si)<sub>2</sub>Ni(PMe<sub>3</sub>)<sub>2</sub> is also prepared in this way; it has a trigonal

bipyramidal geometry with the F<sub>3</sub>Si ligand occupying the axial positions and having an average Si-Ni bond length of 2.182 Å.<sup>318</sup> The arene complexes ( $\eta^6$ -toluene)Ni(SiF<sub>3</sub>)<sub>2</sub> and ( $\eta^6$ -benzene)Ni(SiCl<sub>3</sub>)<sub>2</sub> react with CO to give rare examples of nickel(II) carbonyl complexes, (X<sub>3</sub>Si)<sub>2</sub>Ni(CO)<sub>3</sub> (X = F or Cl). The Cl<sub>3</sub>Si compound has trigonal bipyramidal geometry, with the SiCl<sub>3</sub> group in axial positions, and an average Si-Ni bond length of 2.286 Å; the fluorine analog is likely to have a similar structure.<sup>319,320</sup> Treatment of ( $\eta^6$ -toluene)Ni(SiCl<sub>3</sub>)<sub>2</sub> with alkylammonium salts (Scheme 67) gives the bridged species (29), while treatment with wet di-*t*-butylpyridine affords (30), which has an average Ni-Si distance of 2.171 Å and an Si-N-Si bond angle of 89.9°.<sup>321</sup>

The X-ray structure of F<sub>3</sub>SiCo(CO)<sub>4</sub> (prepared from F<sub>3</sub>SiH and Co<sub>2</sub>(CO)<sub>8</sub>) shows a Si-Co bond length of 2.226 Å, that is, slightly shorter than that in the trichlorosilyl analog (2.254 Å).<sup>322</sup> The Fe-Si distance in ( $\eta^5$ -C<sub>5</sub>H<sub>5</sub>)FeH(SiCl<sub>3</sub>)<sub>2</sub>(CO) is 2.252 Å.<sup>323</sup> The reaction of (PPh<sub>3</sub>)<sub>3</sub>RhCl with Cl<sub>3</sub>SiH gives RhHCl(SiCl<sub>3</sub>)(PPh<sub>3</sub>)<sub>2</sub>, which crystallizes with disordered HSiCl<sub>3</sub> solvate molecules in the lattice. It has a short Rh-Si distance of 2.203 Å, which is again indicative of some back donation of electrons from the metal to the vacant d-orbitals on silicon to give some partial  $\pi$ -bonding.<sup>324</sup>

The UV photolysis of M<sub>3</sub>(CO)<sub>12</sub> (M = Fe, Ru, or Os) with excess Cl<sub>3</sub>SiH gives *cis*- and *trans*-M(CO)<sub>4</sub>(SiCl<sub>3</sub>)<sub>2</sub> (except for M = Ru, when only the *cis* isomer is formed). The CO ligands are readily substituted by PPh<sub>3</sub> or arene ligands to give, for example, *mer*-Ru(CO)<sub>3</sub>(SiCl<sub>3</sub>)<sub>2</sub> and ( $\eta^6$ -Me<sub>3</sub>C<sub>6</sub>H<sub>3</sub>)Ru(CO)(SiCl<sub>3</sub>)<sub>2</sub>.<sup>325</sup> The structure of ( $\eta^6$ -*p*-t-Bu<sub>2</sub>C<sub>6</sub>H<sub>4</sub>)Ru(CO)(SiCl<sub>3</sub>)<sub>2</sub> is of the 'piano stool' type (*see Piano Stool Structure*) having Ru-Si distances averaging 2.339 Å.<sup>326</sup> If M<sub>3</sub>(CO)<sub>12</sub> (M = Ru or Os) are heated at 70–75 °C with Cl<sub>3</sub>SiH, then both M(CO)<sub>4</sub>(SiCl<sub>3</sub>)<sub>2</sub> and the trinuclear M<sub>3</sub>H<sub>3</sub>(CO)<sub>9</sub>(SiCl<sub>3</sub>)<sub>3</sub> are formed.<sup>327</sup>

Various other metal carbonyl complexes react with Cl<sub>3</sub>SiH, with mononuclear silyl complexes being formed from dinuclear starting materials (Scheme 68).<sup>328</sup>

Similarly, photolysis of (PR<sub>3</sub>)Fe(CO)<sub>4</sub> (R = Ph or OPh) with HSiCl<sub>3</sub> gives H(SiCl<sub>3</sub>)(PR<sub>3</sub>)Fe(CO)<sub>3</sub> (via addition

Scheme 67

Scheme 68

of  $\text{Cl}_3\text{Si-H}$  to the 16-electron species  $(\text{PPh}_3)\text{Fe}(\text{CO})_3$ , which when treated with  $\text{PPNCl}$  give  $\text{PPN}$  salts of  $[(\text{SiCl}_3)(\text{PR}_3)\text{Fe}(\text{CO})_3]^-$  anions. Both of the anions are trigonal bipyramidal with both the phosphorus and silicon ligands in axial positions, and Fe-Si distances of 2.197 and 2.206 Å for  $\text{R} = \text{Ph}$  and  $\text{OPh}$ , respectively.<sup>329</sup>

The structures of  $(\text{Cp})(\text{CO})\text{LM}(\text{H})\text{SiR}_3$  complexes ( $\text{R} = \text{Cl}$ ,  $\text{L} = \text{CO}$ , etc.), which are formed in photolytic experiments, are unusual in that they contain Mn-H-Si three-center bonds, for example, (31), in which the Si-H group may be regarded as being bound in an  $\eta^2$ -ligand position. (See Schubert<sup>330</sup> and References 315–317 for a more detailed discussion of  $\eta^2$ -coordination of Si-H bonds to transition metals.)

The salt elimination reaction between transition metal anions and halosilanes also gives the trihalosilyl products (equation 44).<sup>331</sup>

Some of these reactions are slow and give low yields, and  $\text{Cl}_3\text{Si}$  derivatives may more conveniently be prepared by chlorination of a  $\text{SiCl}_2\text{H}$  ligand (equation 45).<sup>332</sup> The structure of  $(\eta^5\text{-C}_5\text{H}_5)(\text{CO})_2\text{FeSiCl}_3$  has an Fe-Si distance of 2.216 Å, while the related compound  $(\text{CO})_4\text{CoSiCl}_3$  has a trigonal bipyramidal structure with  $\text{SiCl}_3$  in an axial position.<sup>333,334</sup>

The reaction between  $\text{MPhCl}(\text{CO})(\text{PPh}_3)_2$  species and  $\text{Cl}_3\text{SiH}$  also gives metal complexes. They undergo substitution reactions with alcohols and alkyllithium reagents to give  $\text{SiR}_3$  species (Scheme 69).<sup>335</sup>

On treatment with three equivalents of water the osmium complex (32) affords the novel complex (33) containing an  $\text{Si}(\text{OH})_3$  ligand (Scheme 70). If only one equivalent of water is used, the bridging disiloxane complex (34) is formed (which is also formed from reaction between (32) and (33) with subsequent hydrolysis). The geometry of (33) is square pyramidal with the  $\text{Si}(\text{OH})_3$  group in the apical position and with an Si-Os distance of 2.319 Å.<sup>336</sup> The relatively recent interest in carrying out chemistry at such a coordinated  $\text{SiX}_3$  ligand would seem to have great potential and further work

Scheme 70

Scheme 69

will undoubtedly see new synthetic routes to compounds unavailable by conventional methods of synthesis.<sup>337</sup>

### 6.3 Compounds Containing Si(OR)<sub>3</sub> Ligands

The iron silyl compounds  $\text{K}[\text{Fe}(\text{CO})_3(\eta^1\text{-Ph}_2\text{PCH}_2\text{PPh}_2)\{\text{Si}(\text{OMe})_3\}]$  and  $[\text{FeH}(\text{CO})_3(\eta^1\text{-Ph}_2\text{PCH}_2\text{PPh}_2)\{\text{Si}(\text{OMe})_3\}]$  react with a variety of other transition metal complexes to give bimetallic compounds in which the  $\text{Si}(\text{OMe})_3$  group may act either to form an  $\eta^2\text{-}\mu_2\text{-SiO}$  bridge or remain as a simple terminal group. For example, reaction of the iron hydride with *trans*- $[\text{PdCl}_2(\text{PhCN})_2]$  affords complex (35) in which the Si–Fe and Pd–O distances are 2.275 and 2.100 Å, respectively, while reaction with  $[\text{Cu}(\text{AsPh}_3)_3]\text{NO}_3$  affords complex (36) which has an Si–Fe distance of 2.282 Å.<sup>338,339</sup>

Oxidative addition of  $(\text{RO})_3\text{SiH}$  occurs (equation 46) when treated with  $\text{RhH}(\text{PPh}_3)_4$  to give the silyl complexes (37).<sup>340</sup>

Similarly, reaction between  $(\text{EtO})_3\text{SiH}$  and  $\text{RhX}(\text{PPh}_3)_3$  ( $\text{X} = \text{Cl}, \text{Br}, \text{or I}$ ) gives oxidative addition products (equation 47).<sup>341</sup>

Oxidative addition of alkoxysilanes to iron complexes also occurs.<sup>342</sup> On further treatment with  $(\text{RO})_3\text{SiH}$ , a second

Scheme 71

carbonyl ligand is lost and a trihydro complex is formed (Scheme 71). The structure of the  $\text{R} = \text{OEt}$  complex is trigonal pyramidal with an Fe–Si distance of about 2.25 Å.<sup>343</sup>

A less well-explored route to  $\text{Si}(\text{OR})_3$  containing complexes is by displacement of another silyl group from the transition metal center or by replacing an alkyl by an alkoxy group at silicon (Scheme 72).<sup>344</sup>

The preparation of transition metal complexes containing silanol groups as ligands can be achieved under mild conditions by oxidation of Si–H groups with dimethyldioxirane. For example,  $\text{Cp}^*(\text{CO})_2(\text{PMe}_3)\text{WSiRH}_2$  may be oxidized to  $\text{Cp}^*(\text{CO})_2(\text{PMe}_3)\text{WSiR}(\text{OH})_2$  (where  $\text{R} = \text{Me}$  or  $\text{OH}$ ) and,  $\text{Cp}(\text{CO})_2(\text{PMe}_3)\text{MoSiH}_3$  affords  $\text{Cp}(\text{CO})_2(\text{PMe}_3)\text{MoSi}(\text{OH})_3$ .<sup>345–347</sup>

### 6.4 Clusters Containing Silicon

Silicon forms a variety of compounds containing clusters of transition metal atoms that exhibit a wide range of structures. Disilane reacts with  $\text{Co}_2(\text{CO})_8$  to give the cobalt cluster (38) in which the silicon is coordinated to five Co atoms (equation 48). The Si···Si distance of 2.817 Å is too long for a bond (normally about 2.35 Å) and the Si–Co distances average 2.336 Å.<sup>348</sup>

Scheme 72

The reaction between  $\text{SiI}_4$  and  $\text{NaCo(CO)}_4$  (equation 49) gives cobalt cluster (39) in which the silicon is coordinated to four cobalt atoms, the  $\text{Si-Co(CO)}_3$  distances averaging  $2.218 \text{ \AA}$  and the  $\text{Si-Co(CO)}_4$  distance being  $2.288 \text{ \AA}$ .<sup>349</sup> The reaction of  $\text{SiH}_4$  with  $\text{Co}_2(\text{CO})_8$  (equation 50) gives the spiro complex (40) in which the  $\text{Si-Co}$  distance averages  $2.288 \text{ \AA}$ .<sup>350</sup> Similarly, the reaction between  $\text{SiI}_4$  and  $\text{NaM(CO)}_5$  ( $\text{M} = \text{Mn}$  or  $\text{Re}$ ) leads to tri- and tetra-substituted products (equation 51).<sup>351</sup>

In a similar manner to the cobalt case,  $\text{SiH}_4$  reacts with  $\text{Fe}_2(\text{CO})_9$  (equation 52) to give a spiro complex (41) containing no bridging COs and with an average  $\text{Fe-Si}$  distance of  $2.345 \text{ \AA}$ .<sup>352</sup>

Reaction of  $\text{SiH}_4$  with a mixture of iron carbonyl complexes (equation 53) leads to a mixed ligand cluster (42) in good yield in which the average  $\text{Si-Fe(CO)}_3$  distance is  $2.306 \text{ \AA}$  and the  $\text{Si-Fe(CO)}_2\text{Cp}$  average distance is  $2.250 \text{ \AA}$ .<sup>353</sup>

The reaction between  $\mu_4\text{-Si[Co}_2(\text{CO})_7\text{]}_2$  and  $[\text{NEt}_4][\text{Co(CO)}_4]$  affords an unusual mixed salt,  $[\text{NEt}_4][\mu_8\text{-SiCo}_9(\text{CO})_{21}][\text{Co(CO)}_4]$  (43). The silicon is encapsulated in

the  $[\mu_8\text{-SiCo}_9(\text{CO})_{21}]^{2-}$  anion and lies almost equidistant from eight of the Co atoms in a capped square-antiprism with an average  $\text{Si-Co}$  distance of  $2.299 \text{ \AA}$ .<sup>354</sup>

(43) A view of the  $[\mu_8\text{-SiCo}_9(\text{CO})_{21}]^{2-}$  anion (the CO groups are omitted for clarity)

## 6.5 Transition Metal Silylyne Complexes

Simple, terminal silylyne complexes,  $\text{L}_n\text{M}\equiv\text{SiR}$ , are very rare. However, as in the case of silylene ligands, the presence of a donor ligand at silicon greatly enhances the stability of such species. Thus, displacement of a good leaving group from silicon (equation 54) affords complexes (44) in which the silicon is coordinated by the bidentate donor ligands. The  $\text{Si-Ru}$  distance in the phenanthroline adduct is  $2.269 \text{ \AA}$  which is, as would be expected, rather short although there are few compounds available with which to make comparisons. The  $\text{Si}\cdots\text{N}$  distances are over  $1.9 \text{ \AA}$ , which clearly indicates a dative coordination rather than the presence of an  $\text{Si-N}$   $\sigma$  bond.<sup>355</sup>

## 6.6 Transition Metal Silylene Complexes

The preparation of several three-coordinate silylene complexes has been discussed in Section 4. A variety of

four-coordinate complexes, (45), are also known in which the silicon is coordinated by a donor molecule such as HMPA or THF. These complexes are all formed by the salt elimination method, the dianions  $[\text{Fe}(\text{CO})_4]^{2-}$ ,  $[\text{Cr}(\text{CO})_5]^{2-}$ , and  $[\text{W}_2(\text{CO})_{10}]^{2-}$  reacting with the appropriate  $\text{R}_2\text{SiCl}_2$  compound. Treatment of  $\text{SiCl}_4$  with two equivalents of  $[\text{Na}_2\text{Fe}(\text{CO})_4]$  similarly gives (46). These and other silylene complexes are discussed more fully elsewhere.<sup>56,57,294,356</sup>

$\text{M} = \text{Fe}$ ,  $n = 4$ ;  $\text{R} = \text{O}-t\text{-Bu}$ ,  $\text{S}-t\text{-Bu}$ , or  $\text{Cl}$

$\text{M} = \text{Cr}$ ,  $n = 5$ ;  $\text{R} = \text{O}-t\text{-Bu}$ ,  $\text{Cl}$ , or  $\text{OCH}_2-t\text{-Bu}$

$\text{M} = \text{W}$ ,  $n = 5$ ;  $\text{R} = \text{O}-t\text{-Bu}$

The bulky stable silylenes described in Section 3 may be used as ligands in a range of transition metal complexes. The complexes are formed mostly via simple ligand displacement reactions as shown in Scheme 73 although in some cases reactions occur involving reduction of halogenometal complexes.<sup>43</sup>

The chemistry of silylene complexes has become much more developed in the past 10 years as silylene complexes have been found to be important intermediates in reactions such as the dehydrogenative coupling of hydrosilanes, redistribution reactions, and the 'Direct Process' for the production of simple chlorosilanes. For reviews of this work, see References 43, 44 and 294. Several complexes have now been prepared in which there is a silene or disilene ligand ( $\text{R}_2\text{C}=\text{SiR}_2$  or  $\text{R}_2\text{Si}=\text{SiR}_2$  species)<sup>56,57</sup> but, since all these contain several Si-C bonds, they will not be discussed further here.

## 7 COMPOUNDS CONTAINING SILICON WITH HIGHER COORDINATION NUMBERS

There are a large number of five- and six-coordinate silicon compounds, the extensive chemistry of which has been reviewed.<sup>357-359</sup> Many of these compounds contain Si-C bonds and so will not be described here. The study of such compounds is of interest because of the lack of analogous carbon chemistry and because of the intermediacy of species with greater than four-coordination in a variety of reaction mechanisms proposed for silicon. (Compounds containing seven-coordinate silicon are known; they usually have an Si-H group present and contain Si-C bonds. Such compounds are described in Reference 357.) There are also a small number of compounds containing silicon with even higher coordination number. For example,  $\text{Mg}_2\text{Si}$  has the antiferite structure and eight-coordinate silicon and the cluster (43) in Section 6.4, contains Si coordinated by nine Co atoms.<sup>354</sup> Calculations on the structures of  $\text{SiX}_5$  and  $\text{SiX}_6$  species ( $\text{X} = \text{H}$  or alkali metal) are discussed in Reference 5.

### 7.1 Five-coordinate Compounds

The most widely studied of the neutral five-coordinate silicon compounds are the so-called 'silatranes' of general structure (47). They are of interest both because of their unusual structure, which incorporates a strong transannular  $\text{N} \rightarrow \text{Si}$  bond, and because of their apparent physiological properties.<sup>360</sup>

The silatranes are generally prepared by reaction of  $\text{N}(\text{CH}_2\text{CH}_2\text{OH})_3$  with an  $\text{RSi}(\text{OR}')_3$  species ( $\text{R}$  = alkyl, aryl, etc.,  $\text{R}'$  = Me or Et). Most of the silatranes have organic  $\text{R}$  groups and so will not be further discussed here. Silatranes may also be prepared by reaction of triethanolamine with a silsesquioxane  $(\text{RSiO}_{1.5})_n$  in the presence of a catalytic amount of  $\text{KOH}$ .<sup>361</sup> The reaction of silatrane itself with *cis*- $[\text{PtCl}_2(\text{PMe}_2\text{Ph})_2]$  gives complex (48), in which there is a very long  $\text{Si} \cdots \text{N}$  distance and a planar nitrogen (equation 55). This, together with IR data, suggests that there is no strong  $\text{N} \rightarrow \text{Si}$  interaction in the complex and that the silicon is four coordinate.<sup>362</sup>

The reaction of  $\text{N}(\text{CH}_2\text{CH}_2\text{OH})_3$  with  $(\text{EtO})_4\text{Si}$  affords ethoxysilatrane (49), which is remarkably stable towards solvolysis. It does, however, undergo reaction (equation 56) with carboxylic acids to give esters (50).<sup>363</sup>

Reaction of ethoxysilatrane with a further equivalent of  $\text{N}(\text{CH}_2\text{CH}_2\text{OH})_3$  affords (51), which may be hydrolyzed to the silanol (52) (Scheme 74).<sup>363</sup>

The hydridosilane  $\text{HSi}(\overline{\text{CH}_2\text{CH}_2\text{O}})_3\text{N}$  may also be prepared in a similar manner from  $\text{HSi}(\text{OMe})_3$  and triethanolamine; the  $\text{Si-H}$  compound reacts with  $\text{HF}$  to give the fluorosilatrane.<sup>364</sup> The X-ray structure of 1-fluorosilatrane shows a  $\text{N} \rightarrow \text{Si}$  distance of 2.042 Å, a little longer than that of 2.023 Å in the 1-chloro derivative.<sup>365</sup>

The interest in silatrane chemistry has led to the preparation of a range of related five-coordinate cyclic compounds that contain different coordination at the silicon or modification of the ring backbone. The synthesis of most of these compounds is achieved in the same way as the simple silatranes, that is, by the reaction of a trifunctional silane,  $\text{XSiY}_3$  (where  $\text{Y}$  is a labile group such as halide,  $\text{OMe}$ ,  $\text{OAc}$ ) with a suitable trifunctional amine. (Representative examples of this interesting class of compounds are shown in Figure 9 below; their chemistry has been reviewed.<sup>366</sup>)

Although no four-coordinate  $\text{Si}$  compounds have been found to have planar geometry, the five-coordinate anion (53), prepared as shown in equation (57), has a geometry at silicon distorted very much away from trigonal bipyramidal towards square pyramidal geometry. The  $\text{O-Si-O}$  angles across the spirocyclic ring are about  $166^\circ$ ; and  $143^\circ$ .<sup>363</sup> The structures of numerous silatranes have been determined and are discussed elsewhere.<sup>112</sup>

A variety of compounds derived from diethanolamine are also known and may be prepared in a similar way to the silatranes.<sup>112</sup> For example, equation (58) affords (54) in which

Scheme 74

**Figure 9** Cyclic structures related to silatrane

the N  $\rightarrow$  Si distance is rather short, 2.004 Å.<sup>367</sup>

In a similar way, reaction of (56) with  $\text{SiF}_4$  (equation 60) affords (57), in which the Si–N and N  $\rightarrow$  Si distances are again significantly different, being 1.701 and 1.974 Å, respectively.<sup>368</sup>

The reaction (equation 59) between lithium amides and  $\text{SiCl}_4$  affords *N*-substituted silanes. The crystal structures of (55; X = F, Cl) clearly shows the intramolecular coordination of an aromatic nitrogen atom. As would be expected, the Si–N  $\sigma$  bonds are rather shorter (1.732 and 1.737 Å) than the N  $\rightarrow$  Si distances (1.969 and 1.9484 Å for the fluoro and chloro derivatives, respectively).<sup>112</sup>

The reaction of  $\text{H}_2\text{SiCl}_2$  with  $\text{Me}_2\text{NH}$  gives  $\text{ClH}_2\text{SiNMe}_2$ , which is a monomer with four-coordinate Si in the gas phase. However, in the solid state it forms a centrosymmetric dimer in which the silicons are five-coordinate and in which there are two short (1.814 Å) and two long (2.054 Å) Si–N distances.<sup>369</sup> The phosphinimine (58) may be formed in two ways (Scheme 75) and in the solid state is shown to be a dimer, again with five-coordinate silicon atoms. The  $\text{Si}_2\text{N}_2$  ring is planar with trigonal bipyramidal geometry at Si and has Si–N distances of 1.736 and 1.857 Å.<sup>370,371</sup>

The addition of a fluoride ion to various fluorosilanes gives salts with a five-coordinate silicon. Thus  $\text{R}_4\text{NF}$  addition to  $\text{SiF}_4$  affords  $[\text{R}_4\text{N}][\text{SiF}_5]$  (R = Et or Pr).<sup>372</sup> A crystallographic study of  $[\text{PhCH}_2\text{NMe}_3][\text{SiF}_5]$  shows the silicon to have trigonal bipyramidal geometry.<sup>373</sup>

Scheme 75

## 7.2 Six-coordinate Compounds

A wide range of adducts between halosilanes and tertiary amines are known. They are formed by mixing the amine and the halosilane and are usually white solids. For example,  $\text{SiF}_4$  and  $\text{SiCl}_4$  form 1:2 adducts with pyridine,  $\text{SiH}_2\text{Br}_2$  forms a 1:4 adduct with pyridine,  $\text{H}_2\text{SiH}_2$  forms a 1:1 adduct with  $\text{Et}_3\text{N}$ , and  $\text{HSiCl}_3$  forms a 1:1 adduct with  $(\text{Me}_2\text{NCH}_2)_2$ .<sup>374</sup> Many of these adducts are ionic; for example,  $\text{SiH}_2\text{I}_2 \cdot 4\text{py}$  may better be represented as  $[\text{SiH}_2 \cdot 4\text{py}]^{2+} 2\text{I}^-$ , but the fluorosilane compounds are neutral adducts.<sup>375</sup>

The molecular structure of  $\text{SiF}_4 \cdot 2\text{py}$  (**59**) shows a centrosymmetric octahedral geometry at silicon with the pyridine molecules trans to each other and an Si–N distance of 1.93 Å.<sup>376</sup> Hexacoordinate geometry may also occur when using a chelating ligand such as bipyridine as in complex (**60**), where the N → Si distance averages 1.977 Å.<sup>377</sup>

The alkali metal salts of the six-coordinate anion (**61**) may readily be prepared (equation 61) by using  $\text{SiO}_2$  (or  $\text{Si}(\text{OMe})_4$ ) as starting material, thus forming monomeric silicon compounds from the polymeric  $\text{SiO}_2$  without the need for the isolation of elemental silicon.<sup>378</sup>

The catechol derivatives (**64**) are versatile synthetic intermediates and they form readily with Grignard or alkyllithium reagents (equation 62). The products formed depend on the solvent and the nature of the R group but species (**62**) or (**63**) may be produced, the latter being formed when R is allyl, vinyl, alkynyl, or phenyl.<sup>378</sup>

The catechol derivatives (**64**) are useful synthetic intermediates as they react with a variety of readily available reagents to give products as shown in Scheme 76.<sup>378</sup>

The tris(catecholate) complex (**61**) also reacts with  $\text{LiAlH}_4$  to give  $\text{SiH}_4$ .<sup>378</sup> The structure of the tris(catecholate) complex  $[\text{C}_5\text{H}_5\text{NH}]_2[(\text{C}_6\text{H}_4\text{O}_2)_3\text{Si}]$  has a slightly distorted octahedral symmetry for the dianion, with the O–Si–O angles being slightly less than  $90^\circ$ .<sup>379</sup>

Silicon, like many other elements, readily forms acetylacetonato (acac) complexes. Thus, reaction of  $\text{SiCl}_4$  with 2,4-pentanedione (Scheme 77) affords the six-coordinate monocation (**65**). Other complexes may readily be prepared by addition of appropriate metal salts.<sup>380</sup>

Scheme 77

Scheme 76

The tris(oxalate) complex (66), which is very soluble in MeOH, may also be readily prepared (equation 63) using silver oxalate.<sup>381</sup>

Tris chelate complexes such as  $[(\text{acac})_3\text{Si}]^+$  and (61) are potentially optically active and may be resolved by crystallization of suitable tartrate salts.<sup>382,383</sup> The reaction of  $[\text{NF}_4][\text{HF}_2]$  with  $\text{SiF}_4$  (equation 64) affords the six-coordinate (67) as a white crystalline solid that is stable at room temperature but decomposes at  $90^\circ\text{C}$ .<sup>384</sup>

The partial hydrolysis of  $\text{SiI}_4(\text{bipy})_2$  affords  $[\text{Si}(\text{OH})_2(\text{bipy})_2]\text{I}_2 \cdot 2\text{H}_2\text{O}$ , in which the cation has *cis* octahedral geometry and each OH group is hydrogen bonded to one of the water molecules.<sup>385</sup>

The mixing of silicon tetrahalides with simple Lewis bases such as  $\text{NMe}_3$  ( $\text{NH}_3$  would react with Si, Cl, Br, or I bonds) or  $\text{PMe}_3$  leads to the formation of a variety of both five- and six-coordinate complexes, for example,  $\text{SiF}_4 \cdot n\text{B}$  ( $n = 1$  or  $2$ ,  $\text{B} = \text{PMe}_3$  or  $\text{NMe}_3$ ),  $\text{SiCl}_4 \cdot 2\text{Me}_3\text{P}$ ,  $\text{SiCl}_4 \cdot \text{NMe}_3$ , and  $\text{Br}_4\text{Si} \cdot 2\text{Me}_3\text{P}$ . The geometry of these compounds has been studied in detail by IR and Raman spectroscopy, which suggest that the five-coordinate complexes are trigonal bipyramidal and the six-coordinate are trans octahedral.<sup>386,387</sup> An X-ray structural study of  $\text{SiCl}_4 \cdot 2\text{PMe}_3$  confirmed the trans octahedral geometry, showing Si–Cl bonds of about  $2.25 \text{ \AA}$  and the Si–P distance as  $2.26 \text{ \AA}$ .<sup>388</sup> However, an IR study of  $\text{SiF}_4 \cdot 2\text{NH}_3$  and  $\text{SiF}_4 \cdot 2\text{N}_2\text{H}_4$  suggests a cis octahedral structure for these adducts.<sup>389</sup> Compounds such as  $\text{SiF}_4 \cdot \text{bipy}$  or  $\text{SiF}_4 \cdot \text{en}$  containing bidentate chelating ligands are clearly constrained by the ligand geometry to be cis complexes. Perhalodisilanes and  $\text{Si}_3\text{Cl}_8$  also react with chelating ligands to give 1:1 complexes such as  $\text{Si}_2\text{X}_6 \cdot \text{bipy}$  ( $\text{X} = \text{F}, \text{Cl}$ , or  $\text{Br}$ ),  $\text{Si}_2\text{X}_6 \cdot \text{phen}$  ( $\text{X} = \text{Cl}$  or  $\text{Br}$ ), and  $\text{Si}_3\text{Cl}_8 \cdot \text{bipy}$ . IR and NMR studies suggest that the plane of the chelating ligand is perpendicular to that of the Si–Si axis. In  $\text{Si}_3\text{Cl}_8$ , the bipyridyl ligand coordinates to the more Lewis acidic,  $\text{SiCl}_2$ , silicon.<sup>390</sup>

A range of diiodosilanes react (equation 65) with 2,2'-bipyridine to give ionic complexes (68).<sup>391</sup>

$\text{Si}^{4+}$  ions are found in octahedral complexes containing six neutral ligands such as  $[\text{Si}(\text{pyO})_6]\text{I}_4$  (equation 66).<sup>392</sup>

Phenylene *N*-oxide also forms six-coordinate chelated complexes with  $\text{SiX}_4$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}$ , and  $\text{I}$ ).<sup>393</sup> Six-coordinate

Scheme 78

Scheme 79

$\text{Si}^{4+}$  complexes may also be formed by reacting  $\text{SiI}_4$  with bipyridine or phenanthroline in the melt (Scheme 78). 1-Methylimidazole reacts with  $\text{SiI}_4$  to give a similar complex (Scheme 78).<sup>394</sup>

Tetrafluorosilane is the strongest Lewis acid of the halosilanes and is capable of forming stable adducts with

primary and secondary amines without loss of HX, which would occur with chloro-, bromo-, or iodosilanes (Scheme 79). The adducts are, however, broken down at high temperatures and in the presence of reagents such as  $\text{LiAlH}_4$ ,  $\text{B}_2\text{H}_6$ , and  $\text{NaBH}_4$ .<sup>262,395</sup>

Both  $\text{Na}_2\text{SiF}_6$  and  $(\text{NH}_4)_2\text{SiF}_6$  may be used for the conversion of organosilicon chlorides to fluorides (equation 67).<sup>396</sup>

Porphyrin ligands may also be used to prepare a range of neutral, six-coordinate silicon compounds. Thus, deprotonation of a porphyrin with  $\text{LiN}(\text{SiMe}_3)_2$  affords dianions that react readily with  $\text{HSiCl}_3$  to give the corresponding dichlorides (69). These can then be treated with a variety of salts to give further derivatives (Scheme 80).<sup>397</sup>

Silicon-containing phthalocyanines (70) can form stacks and have interesting optical<sup>398</sup> and conducting properties.<sup>399</sup> The individual macrocycles can be connected via oxygen bridges from the silicon center, organic bridges, or by direct Si–Si bonds.<sup>400</sup>

Scheme 80

## 8 CHARACTERIZATION AND ANALYSIS OF INORGANIC SILICON COMPOUNDS

The compounds of silicon described in this article are generally monomeric and soluble in common solvents. They are, therefore, amenable to study by all of the commonly available methods for molecular characterization such as IR, UV, and NMR spectroscopy, mass spectrometry, and X-ray crystallography. Two of these methods, IR and  $^{29}\text{Si}$  NMR spectroscopy, have been used with particular success.

The characteristic stretching frequencies for all of the common Si–X bonds have been studied in detail but perhaps the most useful is that of the Si–H bond. The Si–H stretch is usually strong and sharp and it occurs in the  $2280\text{--}2080\text{ cm}^{-1}$  region of the IR spectrum, well away from most other bands. The precise position of the Si–H band is sensitive to the electronegativity of the substituents and a more detailed discussion of its position and that of bands due to other Si–X bonds can be found elsewhere.<sup>401</sup>

Silicon only has one naturally occurring isotope ( $^{29}\text{Si}$ ) with a nonzero nuclear spin and  $^{29}\text{Si}$  NMR spectroscopy has become one of the most widely used techniques for the identification of silicon compounds. Unfortunately, the natural abundance of  $^{29}\text{Si}$  is only 4.7%, which combined with its long spin–lattice relaxation times, means that relatively long acquisition times may be needed to obtain high quality spectra.  $^{29}\text{Si}$  NMR spectroscopy has been the subject of a number of reviews and tables of chemical shift data and coupling constants are available.<sup>402–404</sup>

Various methods for the determination of silicon, particularly from biological samples are available. The techniques usually involve decomposition of the compound to give silica or a silicate by either wet combustion or fusion with sodium peroxide. The silicate formed can then be determined colorimetrically, volumetrically, or gravimetrically.<sup>401</sup> Acidified ammonium heptamolybdate reacts only with monomeric  $\text{Si}(\text{OH})_4$  and not its oligomers to give a yellow silicomolybdic acid complex that can be determined spectrophotometrically. This method works

for concentrations in the 1 to 1000 ppm range but concentrations down to 0.1 ppm can be determined if the yellow silicomolybdic acid is reduced to blue silicomolybdic acid.<sup>405,406</sup>

## 1 INTRODUCTION

Silicon exists as the second most abundant element after oxygen, in the form of silicates in the Earth's crust. Berzelius first isolated the element silicon in 1823. In the periodic table, silicon has the position just below carbon. Carbon can be found in nature in a pure state or in a variety of forms of organic compounds, whereas silicon cannot be found in a pure state and constitutes mineral compounds. Thus carbon and silicon characterize the organic and inorganic worlds, respectively. Fundamental atomic properties can be compared with other group 14 elements; some are given in Table 1 (*see also Silicon: Inorganic Chemistry*). Silicon can be described as having an outer electron configuration  $3s^2p^2$ .

Organosilicon compounds can be defined as chemical species having carbon–silicon bond(s). Since there are no organosilicon compounds in nature, all organosilicon compounds are artificial and therefore we can say that human wisdom built organosilicon compounds. Historically, organosilicon compounds have been known since Friedel and Crafts prepared tetraethylsilane by the reaction of diethylzinc and silicon tetrachloride in 1863.

Kipping, who has been frequently mentioned as the founder of organosilicon chemistry, used the Grignard reagents for the preparation of a variety of organosilicon compounds and investigated the properties of a wide range of compounds during the years 1898–1939. This period may be regarded as the first generation in organosilicon chemistry. Kipping summarized his investigation in rather a depressing tone that 'as moreover the few that are known are very limited in

their reactions, the prospect of any immediate and important advance in this section of organic chemistry does not seem to be very hopeful' (Bakerian Lecture, 1936).

It was only after a short time that Eugene Rochow (US) and Richard Müller (Germany) simultaneously discovered the direct synthesis of methylchlorosilanes, in 1941–1942, that led to the booming silicone industry. New reactions and compounds have emerged since then. Perhaps the development until the late 1960s can be called the second generation of organosilicon chemistry. In that time, almost all known types of organosilicon compounds (silicon-functional compounds) were prepared and many fundamental reactions were described.

However, nothing was known of organosilicon reactive intermediates, double- and triple-bonded species, photochemistry, high-molecular weight polysilanes, and silicon polyhedranes. It was not until the late 1960s that organosilicon compounds received much interest as intermediates in organic synthesis. The nature of the effects that organosilicon groups exert on organic compounds was also systematically studied only in the past three decades. The author designates the period after 1970 as the third generation of organosilicon chemistry. Development of the organosilicon chemistry towards materials science is a notable fact from the end of the twentieth century.

The author will try, in this section, to introduce a concise summary of the basic organosilicon chemistry and an essence of the recent development.<sup>1</sup>

## 2 CLASSES OF COMPOUNDS AND NOMENCLATURE

The nomenclature of organosilicon compounds is based on the derivatives of silane, disilane, and higher polysilanes. When the silicon group is used as a substituent (silicon-containing radical), silyl, disilanyl, trisilanyl, and polysilanyl are used:

$\text{SiH}_4$  = silane,  $\text{H}_3\text{Si}-$  = silyl

$\text{SiH}_3\text{SiH}_3$  = disilane,  $\text{H}_3\text{SiSiH}_2-$  = disilanyl

$\text{SiH}_3\text{SiH}_2\text{SiH}_3$  = trisilane,  $\text{H}_3\text{SiSiH}_2\text{SiH}_2-$  = trisilanyl

Note that for  $\text{H}_3\text{SiSiH}_2-$  and  $\text{H}_3\text{SiSiH}_2\text{SiH}_2-$ , disilanyl and trisilanyl should be used instead of disilyl and trisilyl. The latter means two and three silyl groups, respectively. For substituted silanes, substituents are arranged in alphabetical order.  $\text{Me}_2\text{SiCl}_2$  and  $\text{ClCH}_2\text{SiMe}_3$  are named as dichlorodimethylsilane and chloromethyltrimethylsilane. However,  $\text{Me}_3\text{SiCl}$  may be named as either chlorotrimethylsilane or trimethylsilyl chloride. Since hydrogen attached to silicon is a functional group capable of reduction of inorganic as well as organic compounds and *Hydrosilation*, compounds such as  $\text{Ph}_3\text{Si-H}$  and  $\text{Et}_3\text{Si-H}$  are referred to as organosilicon hydrides, specifically as triphenylsilyl hydride and triethylsilyl hydride. The

general name of organosilane does not indicate the presence of the Si–H group.

Compounds having the general formula H<sub>3</sub>Si(XSiH<sub>2</sub>)<sub>n</sub>XSiH<sub>3</sub> have the generic names silazanes (X = NH), silthianes (X = S), and siloxanes (X = O). The name silmethylenes (X = CH<sub>2</sub>) may also be used. Examples are:

- Me<sub>3</sub>Si–NH–SiMe<sub>3</sub> hexamethyldisilazane
- H<sub>3</sub>Si–S–SiH<sub>2</sub>–S–SiH<sub>3</sub> trisilthiane
- Me<sub>3</sub>Si–O–SiMe<sub>3</sub> hexamethyldisiloxane
- Me<sub>3</sub>Si–CH<sub>2</sub>–SiMe<sub>2</sub>–CH<sub>2</sub>–SiMe<sub>3</sub> octamethyltrisilmethylene

Cyclic compounds having the formula (SiH<sub>2</sub>X)<sub>n</sub> are called cyclosilazanes, cyclosilthianes, cyclosiloxanes, and cyclosilmethylenes for compounds with X = NH, S, O, and CH<sub>2</sub>. The oxa-aza convention can be used for complex systems. For example, Me<sub>3</sub>Si–CHPh–SiMe(CH=CH<sub>2</sub>)–O–SiMe<sub>3</sub> may be named 2,2,4,6,6-pentamethyl-5-phenyl-4-vinyl-3-oxa-2,4,6-trisilaheptane.

Simple hydroxy derivatives are named as silanol:

Me<sub>3</sub>SiOH trimethylsilanol  
PhSi(OH)<sub>3</sub> phenylsilanetriol

Silicon-functional compounds are named by using appropriate prefixes or suffixes. Me<sub>3</sub>SiNH<sub>2</sub> is trimethylsilylamine or aminotrimethylsilane. Organic compounds with silyl substituent(s) are usually named by organic nomenclature. Thus Me<sub>3</sub>SiCH<sub>2</sub>CN is named trimethylsilylacetonitrile. In organic chemistry, trimethylsilyl is often abbreviated as TMS. Thus TMSOEt indicates ethoxytrimethylsilane.

For commercially important methylsiloxanes and polysiloxanes (silicones), a shorthand siloxane notation is used. Mono-, di-, tri-, and tetra- (quaternary) functional Me<sub>3</sub>SiO<sub>1/2</sub>-, –O<sub>1/2</sub>SiMe<sub>2</sub>O<sub>1/2</sub>-, MeSi(O<sub>1/2</sub>)<sub>3</sub>-, and Si(O<sub>1/2</sub>)<sub>4</sub> groups are abbreviated as M, D, T, and Q. Therefore Me<sub>3</sub>Si–O–SiMe<sub>3</sub>, Me<sub>3</sub>Si–(OSiMe<sub>2</sub>)<sub>8</sub>–O–SiMe<sub>3</sub>, and (Me<sub>2</sub>SiO)<sub>3</sub>, are, for example, represented as M<sub>2</sub>, MD<sub>8</sub>M, and D<sub>3</sub>, respectively.

Table 2 lists representative classes of organosilicon compounds with a typical example. The same classes of organic compounds are compared in the table.

### 3 SYNTHESIS

The following five types of reactions may prepare organosilicon compounds.

1. Silicon–carbon bond forming reactions.
2. Cleavage of the silicon–carbon bond to give silicon-functionalized silanes.
3. Substitution reactions on silicon to give silicon-functionalized silanes.
4. Preparation of carbon functionalized silanes.
5. Synthesis of polysilanes (silicon–silicon bond formation).

#### 3.1 Silicon–carbon Bond Forming Reactions

##### 3.1.1 Direct Synthesis (The Rochow Process)

Direct synthesis is the reaction of alkyl or aryl chloride and silicon in the presence of a proper catalyst. Mostly, methyl chloride is subjected to the reaction at 250–350 °C in a fluid bed with fine particles of silicon mixed with a copper catalyst (equation 2).<sup>2</sup>

Operating conditions are usually optimized to give dichlorodimethylsilane, Me<sub>2</sub>SiCl<sub>2</sub>, required for the production of methylsilicones. Nevertheless, mixtures of chlorosilanes are always obtained, as listed in Table 3. Boiling points being very close each other, an extensive fractionating system is employed to separate these chlorosilanes in the silicone industry.

##### 3.1.2 Reactions of Organometallic Reagents and Si–X

The most important laboratory method of the preparation of particular organosilicon compounds is the reaction of an appropriate chlorosilane and a Grignard reagent (equation 3).

**Table 3** Monomer composition of the direct synthesis products

| Compound                          | % composition <sup>a</sup> | Bp (°C) |
|-----------------------------------|----------------------------|---------|
| Me <sub>4</sub> Si                | 0.01–0.5                   | 26.6    |
| MeSiHCl <sub>2</sub>              | 1–6                        | 41      |
| Me <sub>3</sub> SiCl              | 1–5                        | 58      |
| MeSiCl <sub>3</sub>               | 3–10                       | 66      |
| Me <sub>2</sub> SiCl <sub>2</sub> | 75–93                      | 70      |

<sup>a</sup>Composition of the products depends on operating conditions.

SiCl<sub>4</sub>, SiHCl<sub>3</sub>, and various methylchlorosilanes are used in the reaction. When silicon carries more than two chlorine atoms, stepwise reaction occurs. Therefore partial alkylation (or arylation) is possible under carefully controlled conditions but, for that purpose, alkoxy silanes can conveniently be used because the reactivity of the last alkoxy group toward Grignard reagents is very low (equation 4).

The relative reactivity of SiX toward Grignard reagent is shown in the following order: Si–CN > SiCl > SiOR > Si–OSi > SiH. Poly-Grignard reagents from X–(CH<sub>2</sub>)<sub>n</sub>–X give normal products when *n* is larger than 4. In the case of *n* = 1, in situ Grignard reactions can be utilized (equation 5).

Organolithium compounds can also be used conveniently for the preparation of silanes. Reactivity of the lithium reagents is higher than the corresponding Grignard reagents, as demonstrated by the following example. The reaction of

HSiCl<sub>3</sub> and *i*-PrMgCl results in the formation of *i*-Pr<sub>2</sub>SiHCl, but the reaction with *i*-PrLi gives rise to *i*-Pr<sub>3</sub>SiH. Preparation of *t*-butyldimethylchlorosilane from dimethyldichlorosilane requires the use of *t*-BuLi but an interesting accelerating effect of CN<sup>–</sup> has been observed for the reaction of chlorosilanes with bulky *t*-BuMgCl. The reaction may proceed through a pentacoordinate intermediate (equation 6).<sup>3</sup>

Dilithium reagents derived by reductive coupling of alkenes such as styrene and 1,1-diphenylethylene are important for the preparation of ring compounds (equation 7).

A similar dilithium reagent derived from 1,1-bis(trimethylsilyl)ethylene has been used for the protecting ligand of the first monomeric stannylene<sup>4</sup> (equation 8) and later, of various kinetically stabilized species (vide infra). Cyclooctatetraene undergoes 1,4-disilylation as shown below (equation 9).

Closely related to the Birch reduction, benzene, and other aromatic compounds afforded reduction-silylation products (equation 10).<sup>5</sup> Electron-transfer reactions of bis(phenylethynyl)dimethylsilane gives 2,5-dianion of 3,4-diphenylsilole that is a useful intermediate to variously substituted siloles (equation 11).<sup>6</sup>

Examples using other organometallic reagents are illustrated in equations (12) and (13).

### 3.1.3 Reactions of Silylmetals

Since silicon is a positive element, covalent bonds of most silicon compounds polarize as  $\text{Si}^+-\text{X}^-$ . However, silicon can form bonds with alkaline and alkaline earth metals to give silylmetals in which silicon compounds polarize as  $\text{Si}^--\text{M}^+$ . These silylmetals are the source of silyl anions and react with haloalkanes to give the corresponding organosilanes (equation 14).

Preparation of phenyl-substituted silyl anion is a simple process either from chlorosilanes or disilanes (equation 15).<sup>7</sup> Trimethylsilyl anions can be prepared from hexamethyldisilane by reaction with RM (RM=MeONa,<sup>8</sup> MeLi<sup>9</sup>) in a strongly basic solvent such as HMPA (hexamethyl phosphoramide).

For the purpose of preparing trimethylsilylmetals, DMI (*N,N*-dimethylimidazolidinone) has been introduced as an efficient aprotic solvent. In fact, the choice of the solvent is important for the reaction (equation 14). In HMPA, electron transfer predominates to give products only in low yield, while in DMI the yield is almost quantitative.<sup>10</sup>

Silyllithium compounds may also be prepared by the transmetalation reaction between silylmercury and Li. The requisite silylmercury may be prepared from the corresponding chlorosilane or hydrosilane. The latter can be applied to the synthesis of polysilynyllithium. Equation (17) is an example.<sup>11</sup>

Diethylamino-substituted silyllithium is prepared successfully and used for the preparation of silicon-functional compounds (equation 18).<sup>12</sup>

A combination of trimethylsilyllithium, MeMgBr, and a manganese salt is reported to be equivalent to  $(\text{Me}_3\text{Si})_2\text{MnMe}$  that shows an interesting reaction (equation 19). Further recent development on silyl anion chemistry will be described in Section 5.1.

### 3.1.4 Hydrosilation (Addition of Hydrosilane to Alkenes and Alkynes)

Addition reactions of hydrosilanes to alkenes shown in the following general scheme are one of the most frequently utilized reactions for the preparation of organosilanes (equation 20).<sup>13</sup>

The reactions are further classified into three major categories: radical chain reactions, transition metal catalyzed reactions, and base-catalyzed reactions. In the radical chain reactions, dibenzoyl peroxide, di-*t*-butyl peroxide and  $\alpha,\alpha'$ -azobisisobutyronitrile (AIBN) are used most frequently as an

Scheme 1

initiator. The characteristics of the reaction follow general free-radical reactions. Thus the regiochemistry of addition is an anti-Markovnikov fashion to produce the more stable radical. The trans-addition is generally observed for addition. Relative reactivity of hydrosilanes is determined by the polarity and bond dissociation energy of the Si-H bond. The order of the reactivity is:  $\text{HSiCl}_3 > \text{HSiRCl}_2 > \text{HSiR}_2\text{Cl} > \text{HSiR}_3$ . Reactive hydrosilanes such as  $\text{HSiCl}_3$  are used most commonly (Scheme 1, and equations 21 and 22).

Hydrosilation reactions catalyzed by transition metal complexes have wide scope and applicability and hence used most conveniently for the silicon-carbon bond formation. Chloroplatinic acid, platinum on carbon or alumina, platinum(II) and platinum(0) complexes,  $\text{Co}_2(\text{CO})_8$ ,  $\text{NiCl}_2 \cdot (\text{PPh}_3)_2$  and  $\text{RhCl}(\text{PPh}_3)_3$  are effective catalysts, among others. In particular, chloroplatinic acid,  $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ , known as Speier's catalyst, is the most commonly used and efficient catalyst, especially for the hydrosilation of alkenes. This catalyst, which is used as a solution in isopropyl alcohol, is quite efficient, only a minute amount in the range  $10^{-5}$ – $10^{-8}$  mole per mole of hydrosilane being necessary. Therefore the catalyst is not normally recovered from the product in the commercial process even though platinum is a precious metal. The  $\text{Pt}^0$  catalyst,  $\text{Pt}_2(\text{H}_2\text{C}=\text{CSiMe}_2\text{OSiMe}_2\text{CH}=\text{CH}_2)$ , is also used extensively.

The reaction is also utilized for cross-linking between vinyl-substituted siloxanes and oligomeric hydrosilanes in the production of room-temperature vulcanizable silicone rubber. Reaction can be carried out without solvents, but common solvents such as benzene, toluene, dichloromethane, THF, and acetonitrile can be employed as well. A wide variety of 1-alkenes are hydrosilated regiospecifically to give

the corresponding terminal addition products in high yields. Usually, reactions take place exothermically (equation 23).

Regiospecificity of the reaction is normally high but with some alkenes, such as styrene, considerable amount of the  $\beta$ -isomer (38.5%) is produced exceptionally in addition to the  $\alpha$ -isomer (58.7%). Interestingly, alkenes having an inner double bond undergo hydrosilation with isomerization to give exclusively terminal products, as shown in equation (24).

Isomerization does not take place on the products. No isomerization of alkenes occurs with the action of chloroplatinic acid alone, but recovered alkenes from a silane-alkene mixture often contain isomers of the alkene. D-H exchange is observed for the recovered hydrosilane from the hydrosilation mixture with  $\text{DSiCl}_3$ . These facts suggest the mechanism outlined in Scheme 2, which is known as the Chalk-Harrod mechanism.<sup>14</sup> The mechanism involves oxidative addition of hydrosilane to the active species of the catalyst, coordination of alkene, followed by  $\sigma - \pi$  conversion, and reductive elimination of the product.

The Chalk-Harrod mechanism has been accepted for many years as a typical example of a homogeneous catalysis process. However, it has been recently suggested that the formation of colloidal platinum could be the key step in the action of Speier's catalyst.<sup>15</sup> Hydrosilation reactions with other catalysts such as  $\text{Co}_2(\text{CO})_8$ ,  $\text{NiCl}_2(\text{PPh}_3)_2$ , and  $\text{RhCl}(\text{PPh}_3)_3$  are definitely homogeneous and probably follow the Chalk-Harrod mechanism. The step of reductive elimination is indicated to go with retention of configuration on carbon, the overall stereochemistry at silicon being also retention. Acetylenes gave syn addition products as shown in equations (22) and (25).

Alkenes with a variety of substituents such as acetal, amine, amide, carbamate, ester, ether, isocyanate, ketone, oxirane, and sulfide can be hydrosilated, usually without affecting the functional group. However, this is not always true; for example, allyl chloride gives a considerable amount of the reduction product (see equation 26). Table 4 lists representative examples of hydrosilation. It is not so remarkable in the case of radical hydrosilation, but reactivity is high for hydrosilane, which has electronegative group in the case of transition metal catalyzed hydrosilation.

Scheme 2

**Table 4** Hydrosilation of unsaturated compounds

| Unsaturated compound                                                     | Hydrosilane           | Catalyst                         | Product (% yield)                                                                                                |

The  $[2\sigma + 2\pi]$  addition reaction of disilanes and acetylenes is closely related to hydrosilation. The prototype of the reaction is shown in the next example (equation 27).<sup>16,17</sup> The cis addition is established similar to hydrosilation.

Base-catalyzed addition is almost limited to the addition of trichlorosilane to acrylonitrile. *t*-Amines and phosphines are used as catalysts (equation 28).

### 3.1.5 Condensation of Hydrosilanes with Hydrocarbons and Halogenated Hydrocarbons

Trichlorosilane reacts with benzene in the vapor phase at 400–500 °C to give trichlorophenylsilane. Reaction temperature falls to 270–350 °C and yield improves by addition of a catalyst such as BF<sub>3</sub> and BCl<sub>3</sub> (equation 29).

Under UV irradiation,  $\text{Cl}_2$  catalyzes the reaction of trichlorosilane and benzene to give phenyltrichlorosilane in yield higher than 87%. The reaction of benzene with dichloromethylsilane gives  $\text{CH}_3(\text{C}_6\text{H}_5)\text{SiCl}_2$  under the similar conditions in 65% yield. It is suggested that a radical process is involved in the reaction. Silation of aromatic compounds with well-defined silyl radicals generated in solution gives detailed information about the nature of homolytic aromatic silation.<sup>18</sup> It is noteworthy that the addition of silyl radicals to aromatics is a reversible process and therefore, product distribution depends on the reaction temperature<sup>19</sup> (Scheme 3).

Dehydrochlorinative coupling of hydrosilane with aryl or alkenyl chloride is utilized in the industrial synthesis of trichlorophenylsilane, methylchlorophenylsilane, trichlorovinylsilane, and dichloromethylvinylsilane (equations 30 and 31). These reactions are usually carried out in the vapor phase at high temperature and accompanied by side reactions such as redistribution and reduction.

The reaction of 2-chloropropene, trichlorosilane, and amine in the presence of a catalytic amount of copper(I) chloride proceeds smoothly under mild conditions to give allyl-trichlorosilane in high yield<sup>20</sup> (equation 32).

### 3.1.6 Other Reactions

A variety of reactions generate new silicon-carbon bonds, although most of them are not utilized in the systematic synthesis of organosilicon compounds. Representative and interesting examples are shown in the following.

(Chloromethyl)trichlorosilane is formed in 60% yield by the reaction of tetrachlorosilane and diazomethane in ether at

low temperature (equation 33).

Second and third methylenations are possible but with increasing difficulty. The reaction of trialkylsilane with a Simmons-Smith reagent gave the methylenation product. The reactivity of tri-*n*-butylsilane toward iodomethylzinc iodide is much higher than cyclohexene. Indeed, trialkylsilanes are good trapping reagents for divalent species such as carbene and silylene (equations 34 and 35).

Methylene insertion into a silicon-silicon bond is also possible for a reactive Si-Si bond (equation 36). Insertion reactions of divalent silicon species, silylene, also occur to the same substrate. Silylene forms a new silicon-carbon bond with a variety of substrates, which will be described later.

## 3.2 Synthesis of Silicon-functionalized Silanes by Cleavage of the Silicon-Carbon Bond

Silicon-carbon bonds are cleaved by the action of various reagents, and electronegative groups such as halogen and alkoxy are introduced into the silicon part. Therefore these reactions are utilized for introduction of functionality into silicon. Cleavage of the Ar-Si bonds is simple with electrophilic reagents. Halodesilation is important for the preparation of chlorosilanes (equation 37).

Arylsilanes undergo ipso-desilylation by electrophilic attack with E-Nu to give Ar-E and Nu-SiR<sub>3</sub>. The reaction is useful for the preparation of both aryl derivatives and silicon-functionalized silanes (equation 38).

Scheme 3

The chlorodemethylation reaction with a 1:1 mixture of acetyl chloride and aluminum chloride is a standard procedure for the preparation of chlorosilanes in the laboratory (equation 39).

In the presence of a catalytic amount of aluminum chloride, hydrogen chloride, or trimethylchlorosilane also undergoes cleavage of the Si–C bond. The latter is an example of a redistribution reaction (equation 40). Facile cleavage of the allyl-silicon bond has been utilized for the preparation of iodotrimethylsilane (equation 41).<sup>21</sup>

The silicon–carbon bond can also be cleaved by strong nucleophiles to give the corresponding carbanions, which may be utilized as the source of carbon nucleophiles in synthesis (equations 42 and 43).

### 3.3 Synthesis of Silicon-functional Silanes by the Substitution Reactions on Silicon

Silicon centers having electronegative group(s) (leaving group(s)) receive nucleophilic attack easily to give the substitution products. Chloro, alkoxy, and sometimes hydride groups are common leaving groups on silicon. Substitution reactions with carbon nucleophiles serve for the formation of carbon–silicon bonds as described in Section 3.1.2. These reactions are mechanistically related to the corresponding reactions at the carbon center, so that  $\text{S}_{\text{N}}1$  and  $\text{S}_{\text{N}}2$  notations are frequently used also for the reaction at silicon center. However, rigorously speaking, it should be noted that  $\text{S}_{\text{N}}$  reactions are defined to the carbon centers. Accordingly, for example, the reaction of  $\text{Me}_3\text{SiCl}$  with  $\text{PhCH}_2\text{Li}$  to give  $\text{Me}_3\text{SiCH}_2\text{Ph}$  should be designated as the  $\text{S}_{\text{E}}$  reaction at the carbon center. It is convenient, however, to assign this reaction as  $\text{S}_{\text{N}}2$  at the silicon center. To give a clear and accurate explanation, these reactions may be designated as  $\text{S}_{\text{N}}2(\text{Si})$  or  $\text{S}_{\text{N}}2\text{-Si}$ . Hydrosilanes also undergo radical chlorination (equation 45). Mechanism and reactive intermediates of these reactions will be described later; here, synthetically useful

examples are listed (equations 44–52).

### 3.4 Preparation of Carbon Functional Silanes

Carbon functional silanes are compounds having substituent(s) with functional group(s) on carbon(s).  $\text{Me}_3\text{SiCH}_2\text{Cl}$ ,  $\text{Me}_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ , and  $\text{Ph}_3\text{SiCOPh}$  are examples. Preparations of these compounds are classified in two ways: (1) introduction of an organic group with functional group(s) to the silicon center, and (2) introduction of functional group(s) to a hydrocarbon substituent of silanes. The former is typically shown in the next two examples. In principle, any group can be introduced into the silicon center, provided that the corresponding lithium or Grignard reagents can be derived for those groups (equations 53 and 54).

The latter is essentially an organic transformation, and all the known reactions can be applied. However, one should bear in mind that the elimination reaction involving the organosilyl group is rather facile with both strong electrophiles and nucleophiles and that the trialkylsilyl group exerts specific electronic effects, which will be described later.

### 3.5 Silicon–Silicon Bond Formation

The formation of the Si–Si bond occupies a special position in organosilicon chemistry. Silicon is one of the few elements, which can form stable catenated compounds. Besides high-molecular weight polysilanes, oligomeric polysilanes are a very important class of compounds that are related to silylenes,

**Figure 1** Isoconfigurational series

organosilylmetals, silicon–silicon double-bonded species, and photochemistry.

Wurtz coupling reactions of chlorosilanes are the main route to the silicon–silicon bonded compounds. For example, hexamethyldisilane can be prepared by refluxing trimethylchlorosilane with lithium sand in THF (97%). Lithium may be substituted by sodium by using a mixture of HMPA–THF as the solvent. Linear and branched oligosilanes can be prepared by the same method (equations 55–57).

The intermediate of the reaction may be the silyl-alkali metal species, so that the reaction of the silyl-alkali metal derivatives with chlorosilane resulted in the formation of the silicon–silicon bonded compound (equation 58).

Silylene insertion into the Si–H bond as well as silylene insertion into the Si–Si bond forms new silicon–silicon bonds (equations 59 and 60).

Finally, the coupling reaction of two silyl radicals gives the corresponding disilane. In this respect, mercury sensitized dehydrogenative coupling of hydrosilane is noteworthy. Other methods of forming polysilanes, related to the formation of high-molecular weight polysilanes, will be described later.

## 4 STRUCTURE AND BONDING

### 4.1 Tetrahedral Compounds

The geometry of most organosilanes is tetrahedral using the  $\text{sp}^3$  hybridized orbitals on silicon. Like carbon, optically active silanes are possible when central chirality exists. A series of monofunctional optically active silanes can be prepared and used for stereochemical studies. These are the methyl(naphthyl)phenylsilyl derivatives, which are commonly abbreviated to  $\text{R}_3\text{Si}^*\text{X}$ .<sup>22</sup> Together with the similar germanium compound, the isoconfigurational series of compounds are shown in Figure 1.

### 4.2 Penta- and Hexacoordination

Contrary to carbon, silicon can form penta- or hexacoordinated compounds. The formation of such higher coordinated silicon compounds is frequently explained in terms of incorporation of d orbitals to form either  $\text{sp}^3\text{d}$  or  $\text{sp}^3\text{d}^2$ . However, a three-center four-electron bond can also describe the bonding. Both descriptions require electronegative substituents for stable complexes. Indeed, higher coordinated silicon compounds are made with electronegative substituents such as Cl, F,  $\text{NR}_2$ , and RO (Figure 2).

Electronegative atoms adjacent to silicon would contract the d orbitals and transfer electrons to form a dative bond. This concept is called  $p\pi\text{--}d\pi$  or  $(p\text{--}d)\pi$  bonding (*see  $p\pi\text{--}d\pi$  Bonding*) and has been used to explain a number of unique

**Figure 2** Penta- and hexacoordinated silicon compounds

**Figure 3** Examples of anomalous bond lengths and angles. Numbers in parentheses are calculated values

structural features such as shorter experimental bond lengths than calculated for Si–O and Si–F, planarity about nitrogen of  $(\text{H}_3\text{Si})_3\text{N}$ , and the wider bond angle of disilazane than dimethylamine.<sup>23</sup> However, there is controversy over the theoretical proposals of (p-d) $\pi$  bonding. The shorter bond lengths of silicon to electronegative elements may be explained by a larger contribution of ionic structures such as  $\text{R}_3\text{Si}^+\text{X}^-$ . Thus contribution of  $\sigma^*-\pi$  conjugation may also be significant (Figure 3), as will be described later.

#### 4.3 $\sigma-\pi$ Conjugation

Organosilicon reactions, which involve carbenium ion formation or development  $\beta$  to silicon, are much accelerated ( $\beta$  effect). This substituent effect of the silyl group is referred as hyperconjugation or  $\sigma-\pi$  conjugation. This effect is extremely important in controlling the regiochemistry and reactivity in a number of reactions in which a positive charge is developing. Reactions of allylsilanes are typical examples and are used extensively in organic synthesis (Scheme 4).<sup>24</sup>

The  $\sigma-\pi$  conjugation effect is spectroscopically best documented in a number of compounds such as allylic and benzylic silanes. The following examples demonstrate the

**Scheme 4**

**Figure 4** Stereoelectronic effect in  $\sigma-\pi$  conjugation

effect most convincingly. Thus ionization potentials (IP) of 1-trimethylsilylindane, where  $\sigma-\pi$  conjugation due to the trimethylsilyl group is possible, is lower than that of 2-silaindane in which the carbon–silicon bond is placed in the  $\pi$  nodal plane and hence  $\sigma-\pi$  conjugation is impossible (Figure 4).

The  $\sigma(\text{Si-Si})-\pi$  conjugation is equally important. The effect was first evidenced by the discovery of unusually large bathochromic shifts in UV spectra of pentamethylvinyl-disilane ( $\lambda_{\text{max}} = 223 \text{ nm}$ ) and phenylpentamethyldisilane ( $\lambda_{\text{max}} = 231 \text{ nm}$ ) compared with those of trimethylvinylsilane ( $\lambda_{\text{max}} = 178 \text{ nm}$ ) and trimethylphenylsilane ( $\lambda_{\text{max}} = 211 \text{ nm}$ ), respectively.<sup>17,25</sup> The importance of  $\sigma(\text{Si-Si})-\pi$  conjugation has been demonstrated also in charge transfer and photoelectron spectra and finally confirmed by the stereoelectronic effect.<sup>26</sup> 1,1,2,2-Tetramethyl-3,4-benzo-1,2-disila-3-cyclopentene has both C–Si and Si–Si bonds in the nodal plane of the  $\pi$  system, so that no  $\sigma-\pi$  conjugation is possible. Indeed, the characteristic  $^1\text{L}_a$  band of Ph–Si–Si at 231 nm disappeared (Figure 5).

#### 4.4 $\sigma^*-\pi$ Conjugation

Silicon can stabilize  $\alpha$ -carbanions or polarized  $\alpha$ -metalloids in spite of the electropositive nature of silicon. Such stabilization has been accounted for involving (p-d) $\pi$  bonding.

**Figure 5** UV spectra of phenyldisilane derivatives showing  $\sigma(\text{SiSi})-\pi$  conjugation

However, more recently, stabilization for  $\alpha$ -carbanions or polarized  $\alpha$ -metalloids is explained in terms of the  $\sigma^*-\pi$  conjugation (Scheme 5).

$\alpha$ -Carbanions or  $\alpha$ -metalloids are important as a source of carbanions and are used frequently in organic synthesis (vide infra).

The trialkylsilyl group exerts effects to appropriately substituted  $\pi$ -electron systems in two ways as electron donor

**Scheme 5**

and acceptor. The  $\text{R}_3\text{SiCH}_2$ -group shows a strong electron-donating effect to the adjacent  $\pi$ -electron systems by the mechanism of  $\sigma(\text{Si}-\text{C})-\pi$  hyperconjugation. For example, photoelectron spectroscopy indicated that the HOMO energy level of trimethylallylsilane was raised from ethylene. On the other hand, the trialkylsilyl group can behave as an electron acceptor to directly bonded  $\pi$ -electron systems owing to  $\sigma^*-\pi$  conjugation. In planar silyl-substituted alkenes, no strong  $\sigma(\text{Si}-\text{C})-\pi$  conjugation exists but a lowering effect to the LUMO was indicated by electron-transmission spectra for vinyltrimethylsilane.

Figure 6 shows relative orbital energies of trimethylvinylsilane and allyltrimethylsilane compared with ethylene.<sup>27</sup> The fact that IP of trimethylvinylsilane is lower than that of ethylene indicates the electron-donating effect of the trialkylsilyl group that is due to the lower electronegativity of silicon than carbon. But at the same time, the LUMO of trimethylvinylsilane is lowered. The HOMO of allyltrimethylsilane is raised relative to ethylene. These facts give the grounds that trimethylvinylsilane is susceptible to nucleophilic attack, whereas allyltrimethylsilane is reactive towards electrophiles.

The steric effect of the trimethylsilyl group is rather small when it stands singly but the cumulative steric effects should

**Figure 6** Relative HOMO-LUMO levels determined by ionization energy (IP) and attachment energy (AE)

**Figure 7** Over-crowded  $\pi$ -electron systems

be very large when the trimethylsilyl group substitutes the molecule extensively. Both tetrakis(trimethylsilyl)ethylene<sup>28</sup> and hexakis(trimethylsilyl)benzene<sup>29</sup> cannot maintain the  $\pi$ -systems planar to show interesting chemical and physical properties. Olefinic carbons of both tetrakis(trimethylsilyl)ethylene and 1,1-bis(*t*-butyldimethylsilyl)-bis(trimethylsilyl)ethylene are strictly coplanar with silicon substituents but twist of double bonds are 29.5° and 49.6°, respectively. These are most twisted olefins. Hexakis(trimethylsilyl)benzene is a boat-form benzene and undergoes facile isomerization (Figure 7).

#### 4.5 Bond Lengths and Bond Energies

Table 5 lists selected bond lengths of tetracoordinated silicon-element and the corresponding carbon-element bonds. As noted before, the bond lengths for silicon bonded to elements more electronegative than carbon tend to be shorter than the calculated values.

Bond lengths of silicon can also be affected by the coordination number of the compound to some extent. The representative values are listed in Table 6. All the Si–X bonds become longer in higher coordinated states.

Selected bond dissociation energies are compiled in Table 7. Although bond lengths of silicon compounds are longer than the corresponding carbon compounds, silicon forms stronger bonds than carbon.<sup>30</sup>

### 5 REACTIONS AND REACTIVE INTERMEDIATES

Organosilicon compounds receive attack of nucleophilic, electrophilic, and homolytic reagents. The latter is related to the formation of radicals and divalent species. Organosilicon reactive intermediates corresponding to free radicals, carbenium ions, carbanions, and carbenes play important roles in these reactions. These are silyl radicals,<sup>31</sup> silylium

**Table 5** Selected bond lengths for Si–X and C–X

ions,<sup>32</sup> silyl anions,<sup>33</sup> and silylenes.<sup>34</sup> Reaction patterns and reactivities of these reactive intermediates largely resemble those of carbon intermediates. The stereochemistry and mechanism of substitution reactions at silicon can be compared with those at carbon but are much more complicated.

### 5.1 Ionic Reactions

Silylium ions or silico cations are formed more readily than carbenium ions in the vapor phase by electron impact, as evidenced by the fact that the base peak of the mass spectra of trimethylsilyl derivatives is almost always the trimethylsilylium. This means that silicon can support a positive charge more strongly than carbon owing to its more electropositive nature. However, there is too little evidence of the formation of trivalent silylium ions in solution. Two factors may account for the facts: the counter anions normally used to the stabilized carbenium ions (such as perchlorate and tetrafluoroborate) bind to silicon strongly (silicophilic), and bond lengths of silicon and substituents are 1.5 times longer than those of the corresponding carbon compounds, so that the requisite steric congestion for the S<sub>N</sub>1(Si) over the S<sub>N</sub>2(Si) mechanism is lacking. A recent study shows that the attempted generation of silylium ions with nonnucleophilic borate counter anions resulted in the formation of silylium ion-solvent complexes. However, these results do not exclude the generation of ‘free’ silylium ions under proper conditions. Indeed, the crystal structure of Et<sub>3</sub>Si<sup>+</sup> BAr<sub>4</sub><sup>–</sup> (Ar=C<sub>6</sub>F<sub>5</sub>) has been determined, where the interaction of the ‘silylium ion’ with the solvent toluene is minimal (equation 61).<sup>35</sup>

A solvent-free but delocalized silylium ion has been prepared recently.<sup>36</sup> Interestingly, the silylium ion undergoes reversible redox reaction to give the corresponding radical and anion (equation 62).<sup>37</sup> The silylium ion is indicated to be a homotrisilacyclopropenium ion. In fact, 1,3-length of the silylium ion is much shorter than that of the corresponding radical.<sup>38</sup>

With a bulkier substituent (2,4,6-trimethylphenyl = Mes), Mes<sub>3</sub>Si<sup>+</sup> B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub><sup>–</sup> is indicated as an isolated silylium in solution<sup>39</sup> and very recently the cation is proved to be a completely free silylenium ion (equation 63).<sup>40</sup>

The  $S_N2(\text{Si})$  mechanism at silicon is quite common. However, the fundamental difference between carbon and silicon in the  $S_N2$  mechanism is the fact that the pentacoordinate structure with attacking and leaving nucleophiles is not the transition state but an intermediate in silicon, contrary to carbon. In fact, in some cases, stable silicon compounds with the pentacoordinate structure can be isolated (see Figure 2). This fact is mainly due to the longer bond lengths of silicon compounds, where five ligands can be accommodated around the silicon atom.<sup>41</sup> Existence of stable pentacoordinate intermediates makes the stereochemistry of  $S_N2(\text{Si})$  reactions very complicated; not all  $S_N2$  reactions at silicon occur with inversion, while at carbon inversion of the configuration is observed without exception. Thus, the larger size of silicon compared with carbon permits the attack of nucleophiles (*see Nucleophile*) from different directions, not only from the back side to result in inversion but from the flank side to give the retention product (Table 8).

Generally speaking,<sup>42</sup> reactions of silicon compounds with poor leaving groups such as H and OR result in retention of configuration. Inversion occurs only with

strongly charge-delocalized reagents such as  $\text{Ph}_2\text{CHLi}$  (soft nucleophiles), whereas with a good leaving groups like Cl or Br, inversion is observed. The leaving groups F and SR show intermediate behavior, leading to either inversion or retention according to the attacking nucleophiles: inversion with allyllithium, benzyllithium, and  $\text{LiAlH}_4$  (soft nucleophiles), but retention with alkylolithium and alkoxides (hard nucleophiles) (Hard & Soft Acid-base Theory).

The results are best explained in terms of interaction between the HOMO of the nucleophile and the LUMO of the substrate.<sup>43</sup> As shown in Figure 8, the flank-side attack to give the retention product corresponds to the interaction of the nucleophile with the large lobe on silicon. This attack corresponds, at the same time, to interaction with the orbital of the leaving group in an unfavorable out-of-phase fashion. The back-side attack with inversion involves interaction with the small lobe on silicon but no out-of-phase interaction. Determination of the stereochemistry depends on the equilibrium between these two directions. Hard nucleophiles have small, contracted, and high lying valence orbitals, so that overlap with the orbital of the leaving group

**Table 8** Stereochemical behavior of  $\text{R}_3\text{Si}^*\text{-X}$  in the reaction with nucleophiles

| X          | Nucleophile<br>(solvent)                   | Product                                      | Stereochemistry <sup>a</sup> |

<sup>a</sup>RN = retention, IN = inversion.

**Figure 8** Frontier orbital interactions at  $S_N2$  reactions of silicon

is very small to result in the flank-side attack. On the other hand, soft nucleophiles have usually large, diffused, low-lying delocalized orbitals, which may interact equally with orbitals of substrate and leaving group when the flank-side attack occurs. Therefore the back-side attack predominates to favor inversion products.

Silyl anions (silyl-alkali metal derivatives) have been prepared as described in equations (15–17). Reactions of triphenylsilyl anions with electrophiles give the expected products.<sup>44</sup> Silyl anions have a considerable configurational stability (equation 64).

Trimethylsilyl anions also give the substitution products by the reaction with alkyl chloride in almost quantitative yield (equation 14), but considerable amounts of electron-transfer products are produced as well in HMPA. Indeed,  $\text{Me}_3\text{SiNa/HMPA}$  is an excellent reagent to produce anion radicals (Table 9) from aromatic hydrocarbons for ESR (electron spin resonance) studies (equation 65).<sup>45</sup>

Silyllithium forms polymeric structures in the solid state, the structure being dependent on the nature of the silyl group. Trimethylsilyllithium is hexameric with a  $\text{Li}_6$  skeleton of a highly folded chair in the solid state.<sup>46</sup> Pentamethyldisilanyl-lithium is tetrameric with a tetrahedral  $\text{Li}_4$  skeleton. Four pentamethyldisilanyl groups occupy the center of the face to interact with three lithium atoms.<sup>47</sup> The structure of non-solvated monomeric silyllithium,  $(t\text{-Bu}_2\text{MeSi})_3\text{SiLi}$ , is nearly planar. The Si–Si bond lengths are significantly shortened (av. 2.3632 Å) relative to those of  $(t\text{-Bu}_2\text{MeSi})_3\text{SiH}$  (av. 2.450 Å), indicating the existence of hyperconjugation between the central anionic p orbital and adjacent Si–C  $\sigma^*$ -orbitals.<sup>48</sup> Probably, this is also the origin of planarity of the silyl anion similar to the case of trisilylamine.

Silicon-functional silyllithium should be interesting intermediates to a variety of silicon-functional compounds. Chlorine substituted silyllithium is unstable to undergo  $\alpha$ -elimination to give silylenes. Alkoxy-substituted silyllithium may be generated *in situ* reaction conditions and undergoes useful substitution reaction (equation 66).<sup>49</sup>

Diethylamino-substituted silyllithium is much more stable and useful for the preparation of silicon-functional compounds as described before (equation 18).

1,2-Dilithiosilanes have been known.<sup>50</sup> 1,1-Dilithiosilanes are interesting species and silole dianion was first reported.<sup>51</sup>

1,1-Dilithiosilanes with bulky substituents such as Tbt(Dip)SiLi<sub>2</sub> (Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl, Dip = 2,6-diisopropylphenyl)<sup>52</sup> and (i-Pr<sub>3</sub>Si)<sub>2</sub>SiLi<sub>2</sub><sup>53</sup> have been reported recently.

## 5.2 Homolytic Reactions (Silyl Radicals and Silylenes)

Silyl radicals can be generated most conveniently by hydrogen abstraction from the corresponding hydrosilane.<sup>29</sup>

ESR spectra of several silyl radicals have been recorded and the <sup>29</sup>Si hyperfine coupling constants indicate that silyl radicals are nonplanar, contrary to organic radicals. Table 8 lists ESR data of representative silyl radicals. Comparison of ESR data of Ar<sub>3</sub>M• (Ar = 3, 5-di-*t*-butylphenyl, M = C, Si, and Ge), which give relatively stable radicals, is interesting. The *g* values and hyperfine coupling constants, *A*<sub>o-H</sub> and *A*<sub>p-H</sub> (in Gauss), are as follows: Ar<sub>3</sub>C• (−40 °C), 2.0026, 2.58, 2.80; Ar<sub>3</sub>Si• (−50 °C), 2.0027, 0.95, 1.17; Ar<sub>3</sub>Ge• (−70 °C), 2.0056, 0.60, 0.95. The spin densities at the central atoms of Ar<sub>3</sub>M• are estimated to be 0.50 (M = C), 0.78 (M = Si), and 0.82 (M = Ge), indicating increasing nonplanarity with increasing localizing spin density on the central atom from carbon to germanium (equation 70).<sup>54</sup>

Generation of stable (persistent) silyl radicals has been an interesting target. Ph<sub>3</sub>Si• is, contrary to Ph<sub>3</sub>C•, not persistent owing to longer Si–C bond lengths and tendency to undergo *ipso*-substitution. The trimesitylsilyl radical is fairly persistent to be able to observe good ESR spectra (equation 70). According to the general trick to elongate the lifetime of the free radicals, introduction of bulkier substituents produces longer-lived radicals such as triisopropylsilyl radical.<sup>55</sup> The (*t*-BuMe<sub>2</sub>Si)<sub>3</sub>Si• radical is shown to be much more persistent in solution<sup>56</sup> and finally (*t*-Bu<sub>2</sub>MeSi)<sub>3</sub>Si• has been isolated as a crystal.<sup>57</sup> The molecular structure is shown to be planar. One-electron oxidation of the corresponding silyl anion or one-electron reduction of the corresponding bromosilane is better than hydrogen abstraction to produce radicals because of lesser steric requirement in the reaction.

The reaction of silyl radicals with haloalkanes constitutes the H/halogen exchange reaction together with the hydrogen abstraction reaction (equations 69 and 71) but, alternatively, the reaction is also convenient for the production of alkyl radicals. A number of alkyl radicals have been generated and studied by ESR. Interestingly, the silyl radicals derived from an optically active hydrosilane undergo chlorine abstraction reaction mostly with retention of configuration.<sup>58</sup>

The configurational stability of the silyl radical may be best explained in terms of the pyramid structure and slower rate of inversion than abstraction of chlorine. The origin of the pyramidal structure of the silyl radical is the difference between electronegativities of central and substituent elements. This argument may be supported by the following evidence. Thus in the case of fluorinated methyl radicals, •CH<sub>3</sub>, •CH<sub>2</sub>F, •CHF<sub>2</sub>, and •CF<sub>3</sub>, structures change from planar to almost tetrahedral.<sup>59</sup> The planar structure (and low inversion barrier) of (*t*-Bu<sub>2</sub>MeSi)<sub>3</sub>Si• may depend on there being no difference in electronegativities between central and substituent elements. Delocalization of unpaired electron owing to σ\*-p conjugation should contribute to some extent. On this matter, it is noteworthy that chiral disilanyl radical undergoes chlorine abstraction from carbon tetrachloride with retention of

configuration but in low optical yield.<sup>60</sup>

Addition of the silyl radical to carbon–carbon double bonds is an elementary reaction of radical hydrosilation (Scheme 1). Homolytic aromatic silation also occurs involving silyl radicals. Silyl radicals are nucleophilic owing to the high SOMO energy, as evidenced by the directive effects in the homolytic aromatic substitution.<sup>17,61</sup> The intermediate cyclohexadienyl radicals have been observed by ESR.

Addition of the silyl radicals to carbonyl compounds occurs at the oxygen site (equations 75 and 76). The latter reaction is utilized also for spin trapping of silyl radicals (equation 76).

Recently, radicals have increasingly been used in organic synthesis, especially for cyclization of alkenyl radicals generated from the corresponding halides. Tin hydrides have been used for this purpose before but  $(\text{Me}_3\text{Si})_3\text{SiH}$  is now used because it is environmentally safer.

Silylenes, the silicon analogs of carbenes, may be generated thermally<sup>62</sup> and photochemically<sup>63</sup> from appropriate polysilanes (equations 77 and 78).

Other important reactions for generating silylenes are shown in equations (79),<sup>64</sup> (80)<sup>65</sup> and (81).<sup>66</sup>

Major reaction patterns of silylenes are insertion into the O–H (equation 82), Si–H (equation 59) and Si–Si bonds (equation 60), addition to multiple bonds (equation 83), rearrangement (equation 84), and dimerization. Dimerization of the bis(mesityl)silylene (equation 85) opened a pathway to the first isolable disilene.<sup>67</sup>

Ar = mesityl (2,4,6-trimethylphenyl)

Silylenes with two different substituents,  $\text{R}^1\text{R}^2\text{Si}$ , are prochiral, and insertion into an alcoholic RO–H bond should create chirality on the silicon. In particular, if one of the two substituents is chiral, a diastereotopic face can be defined and diastereoselective addition can be expected. Quite recently, the first example of diastereoselective addition of alcohol to diastereotopic silylene has been reported.<sup>68</sup>

Even if it is not as stable as heavier members of the 14 group elements, divalent silicon species has some stability. Isolation of stable silylenes has been an interesting target in organosilicon chemistry. The first stable Si(II) species is silicocene,  $(\text{Me}_5\text{C}_5)_2\text{Si}$ , shown below.<sup>69</sup>

More recently, remarkably stable five-membered silylenes are reported (Figure 9).<sup>70</sup>

In these silylenes, electron donation to the vacant orbital of the silylenes from adjacent nitrogen atoms ( $n\text{-}\pi$  conjugation) should be the important factor in addition to the steric protection by bulky groups. It is interesting to argue whether stabilization owing to the aromaticity ( $6\pi$  electron system) for the unsaturated cyclic silylene (4 electrons from 2 nitrogen lone pair and  $2\pi$  electrons from the double bond) really exists. It is suggested that unsaturated silylene is  $58 \text{ kJmol}^{-1}$  more stable than the saturated analog. Nonetheless, the saturated cyclic silylene is a fairly stable and unreactive species.

Similar cyclic and sterically protected silylene has been prepared recently (equation 88).<sup>71</sup> The silylene must be stabilized to some extent by  $\sigma\text{-}\pi$  conjugation instead of  $n\text{-}\pi$  conjugation for other stable cyclic silylenes shown in Figure 9. Indeed the silylene undergoes facile rearrangement (equation 88).

Figure 9 Stable five-membered silylenes

The carbon analog of silylenes, carbenes  $\text{R}_2\text{C}$ , can be either singlet or triplet electronic ground state depending on the electronic and steric characteristics of the substituents on the carbene center. Silylenes behave mostly as singlet species. In spite of several efforts, no clear evidence for the possibility of a triplet ground state of silylenes.<sup>72</sup> Bulky substituents should widen the bond angle to stabilize the triplet state. Thus it is predicted by computational studies that  $(t\text{-Bu}_3\text{Si})_2\text{Si:}$  has a triplet ground state.<sup>73</sup> According to this prediction, very recently,  $(t\text{-Bu}_3\text{Si})_2\text{Si:}$  has been generated by the photolysis of the corresponding silacyclopentene (equation 89). The ESR spectra as well as its chemical behavior indicate a triplet ground state for the silylene.<sup>74</sup>

### 5.3 Formation and Reactions of Multiply Bonded Species

Because of the close relationship between silicon and carbon, many attempts have been made to try to synthesize species containing multiple bonds to silicon ( $\text{Si}=\text{C}$ ,  $\text{Si}=\text{O}$ ,  $\text{Si}=\text{Si}$ , etc.). However, it was not until 1967 that compelling evidence was presented that  $\text{Si}=\text{C}$  might exist in the thermal reaction of 1,1-dimethyl-1-silacyclobutane (equation 90).<sup>75</sup> The first evidence for the existence of  $\text{Si}=\text{Si}$  as transient intermediate was provided in the thermolysis of bridged disilane derivatives (equation 91).<sup>76</sup> Since then, many studies have been published on these unsaturated species, but it was in 1981 that synthesis and characterization of relatively stable crystalline compounds containing  $\text{Si}=\text{C}$  (silene) (equation 92)<sup>77</sup> and  $\text{Si}=\text{Si}$  (disilene) (equation 85) were reported (equations 90–92).

Until now, the chemistry of multiply bonded silicon has developed explosively. Methods of generation, reactivity, and structure of compounds containing multiply bonded silicon are well documented in reviews.<sup>78</sup> These are R<sub>2</sub>Si=SiR<sub>2</sub> (disilene), R<sub>2</sub>Si=CR<sub>2</sub> (silene), R<sub>2</sub>Si=NR (silanimine), R<sub>2</sub>Si=O (silanone), R<sub>2</sub>Si=P (silaphosphene), and R<sub>2</sub>Si=S (silanethione). Typical reactions of disilenes and silenes are summarized in Schemes (6) and (7).

Scheme 6

Scheme 7

Scheme 8

Existence of geometric isomerism and estimate of the rotational barrier are fundamental properties of double bonds. Not only thermally stable disilenes but reactive disilenes such as *cis*- and *trans*-PhMeSi=SiPhMe can retain geometrical configuration during the reaction.<sup>79</sup> As shown in Scheme 8, *trans*-1,2-diphenyldimethyldisilene can be trapped with anthracene with retention of configuration (96:4) at 300 °C. A similar result was obtained with the *cis* precursor to give the product of configurational retention (94:6). Slightly less stereospecific results were obtained by increasing the temperature to 350 °C. Activation energy of at least  $25.8 \pm 5 \text{ kcal mol}^{-1}$  is calculated for the *cis*-*trans* isomerization.<sup>80</sup>

Notable advances in the last decade are isolation of kinetically stabilized silicon-containing double-bonded species.<sup>81</sup> As we have seen already, a variety of sterically bulky substituents have been utilized to stabilize silicon-centered reactive intermediates. This kinetic stabilization is the key issue also to isolate silicon double-bonded species. For example, the synthesis of isolable silicon analog of benzene and other aromatic compounds has been a target for a long time. One example is shown below for the generation of transient silabenzene.<sup>82</sup>

By using a very bulky substituent, Tbt (2,4,6-tris[bis(trimethylsilyl)methyl]phenyl), 2-silanaphthalene,<sup>83</sup> silabenzene<sup>84</sup> and other related compounds are prepared (Figure 10).

Tetrasilabutadiene,<sup>85</sup> trisilacyclopentene (cyclotrisilene), and tetrasilacyclobutene (cyclotetrasilene) are isolated and the structures are determined by X-ray crystallography.<sup>86</sup>

Compounds of triply bonded silicon or *sp*-hybridized silicon have been indicated as intermediates in some reactions,<sup>87</sup> but they have been elusive for a long time. Very recently, a trisilaallene derivative with a formally *sp*-hybridized silicon atom has been isolated as a stable crystalline compound (equation 94).<sup>88</sup> Contrary to linear original allenes, the trisilaallene is a bent molecule.

Figure 10 Kinetically stabilized silaarenes

More recently, a stable compound containing a silicon–silicon triple bond (disilyne) has been isolated as emerald green crystals (equation 95).<sup>89</sup> 1,1,4,4-Tetrakis[bis(trimethylsilyl)methyl]-1,4-diisopropyl-2-tetrasilyne is thermally stable up to 100 °C in the absence of air. The observed Si–Si triple bond length is 2.0622(9) Å, which is shorter than the average Si–Si (2.39 Å, Table 6) and Si=Si (2.14 Å)<sup>81</sup> but the degree of shortening is smaller than those observed for carbon analogs. In fact, the disilyne is not a linear molecule as acetylene but has a trans bent structure with a bond angle of 137.44(4)°. The disilyne is reactive and reacts with two equivalent of bromine at room temperature to give the starting tetrabromide in 94% yield.

## 5.4 Silicon Polyhedranes

Closely related to disilynes, (RSi)<sub>2</sub>, silicon polyhedranes of the type (RSi)<sub>2n</sub> are also interesting molecules for synthesis. A theoretical consideration of Croup 14 polyhedral compounds, X<sub>n</sub>H<sub>n</sub>, on the level of HF/6-31G\*, where *n* = 4 (tetrahedrane), *n* = 6 (prismane), and *n* = 8 (cubane), suggested that the cubane and prismane structures possess a lower degree of strain energy than the carbon analogs.<sup>90</sup> Thus it may be reasonable to assume that the cubane and prismane analogs of the heavier atoms should be accessible and therefore they are appropriate synthetic targets. However, for the synthesis of strained polyhedranes, proper choice of both starting compounds with a suitable bulky substituent and metals as reducing reagent is of crucial importance, and therefore hexasilaprismane and octasilacubane have been synthesized rather recently.<sup>91</sup> The crystal structures of tetrakis(tri-*t*-butylsilyl)tetrasilatetrahedrane,<sup>92</sup> hexakis(2,6-diisopropylphenyl)hexasilaprismane<sup>93</sup> and octakis(2,6-diethylphenyl)octasilacubane<sup>94</sup> were determined (Figure 11).

Figure 11 Silapolyhedranes

## 6 APPLICATIONS

Organosilicon chemistry has several areas of important applications. Owing to the limitation of the scope of this section, those will be described briefly.

### 6.1 Polymers

#### 6.1.1 Silicones

Silicones are polymers with a polysiloxane backbone. The simplest one is polydimethylsiloxane, MD<sub>n</sub>M, exhibiting the basic structure of the silicones. The methyl group may be substituted by another one such as phenyl, vinyl, and hydrogen. Wohler, who assumed that oxygen was bound to silicon by a double bond similar to that in ketones, introduced the name silicone. Silicones are fluids, resins, or elastomers; they can be greases or rubbers. Silicone oils mostly have the structure of MD<sub>n</sub>M. Rubbers are of the same composition as oils but the degree of polymerization in rubbers is several thousands, much higher than oils. Resins contain T units for the three-dimensional network structure. The initial process of silicone production is hydrolysis of chlorosilanes. Hydrolysis of trimethylchlorosilane gives trimethylsilanol (equation 48) followed by the formation of MM. Hydrolysis of dimethyldichlorosilane is very rapid to give linear and cyclic polysiloxanes depending upon reaction conditions.

Elastomers and nonsilanol terminated fluids are produced by base-catalyzed polymerization of low-molecular weight siloxanes. Polydimethylsiloxanes are also produced by ring opening polymerization of D<sub>3</sub>, D<sub>4</sub>, and D<sub>5</sub>. In the presence of MM or MDDM (endcapper), silicones MD<sub>n</sub>M are formed; otherwise, silanol terminated polysiloxanes may be obtained.

The polydimethylsiloxanes (PDMS) exhibit characteristic properties useful for practical applications: transparent, colorless, thermal stability, oxidative stability, chemical stability, shear stability, dielectric stability, low viscosity change on temperature, nonflammability, low surface tension, high compressibility, water repellant, biologically inactive, and so on. They are used in adhesives, cosmetics, electrical systems, as damping oils, lubricants, polishing oils, in heat exchange, diffusion pumps, textile finishing, and so on. A part of the methyl group of silicones can be replaced by other groups to produce modified silicones, which are now used in almost all industrial products.<sup>95,96</sup>

Silicone rubbers are made by adding an inert filler (mostly silica) to highly viscous PDMS gum, followed by curing in the presence of catalysts. The cure process is a cross-linking reaction of silicone chains and initiated by peroxide (radical process), typically benzoyl peroxide, *m*-chlorobenzoyl peroxide, and di-*t*-butyl peroxide. Major reactions responsible to the cross-linking are generation of free radical and coupling (equation 98). Generation of the SiCH<sub>2</sub>· requires hydrogen abstraction and becomes more difficult when the system becomes more viscous. Then some group such as vinyl is introduced to facilitate the reaction. This process is called heat cure or high-temperature vulcanization (HTV) and the resulting rubber is used in electric, mechanical, automobile, medical, and food industries.

Silicone rubber has a very characteristic and useful way of vulcanization at low temperature. Liquid silicone rubbers of low viscosity polysiloxanes having reactive functional groups, undergo cross-linking by condensation or addition reactions. Cross-linking (curing) can be done at room temperature so that these rubbers are called RTV (room temperature vulcanizing) rubbers. Some typical reactions utilized for the production of RTV are shown in Scheme 9. They find a wide range of applications in molding, sealing, electrical insulation, and so on. People may be familiar with RTV at the dentist for the molding of an artificial tooth and/or inlay.

Silicones are exceptionally thermally stable without acidic or basic substances. Silicones are now used increasingly in cosmetics and personal care fields. Therefore, the fate of silicones (mostly dimethylsilicones) under ambient conditions may be a matter of environmental concern. Fortunately, it is shown that M-D<sub>n</sub>-M polymers depolymerize to Me<sub>2</sub>Si(OH)<sub>2</sub> rather rapidly in soil and water under high dilution conditions. Then Me<sub>2</sub>Si(OH)<sub>2</sub> undergoes stepwise demethylation to T units and finally to Q units (silicic acid). The final degradation of Me<sub>2</sub>Si(OH)<sub>2</sub> to SiO<sub>2</sub> and CO<sub>2</sub> occurs within a few months to year.<sup>97</sup> Therefore, silicones are concluded to be quite safe materials.

Scheme 9

### 6.1.2 Polysilylenes (Polysilanes)

Permethylpolysilylene was prepared in 1949 by the sodium condensation of  $Me_2SiCl_2$ , but the products were insoluble, infusible, and intractable. As a result, these polymers have been neglected until the finding that polydimethylsilylene can be converted to polycarbosilane (PCS) at high temperature by thermal rearrangement. PCS is soluble and meltable. Melt spun PCS fibers can be converted to silicon carbide fibers, which are the most heat-resistant fibers so far.<sup>98</sup> Inspired by this observation, many studies on polysilylenes have been carried out and it was found that homopolysilylenes having substituents other than methyl and most copolymers are soluble. Since then, polysilylenes have been investigated extensively in the past decade because of their potential

applications in the field of materials science.<sup>99</sup> The polysilylenes exhibit characteristic properties useful for practical applications. Applications of polysilylenes in SiC precursors, microlithography,<sup>100</sup> and reprography<sup>101</sup> show that polysilylenes are promising as advanced materials for the high technology of the next generation.

The Si-Si bonds in polysilylenes can also react with a variety of reagents. Typical examples are shown in Scheme 10 in which reactions of hexamethyldisilane, as a model compound, are indicated.

Polysilylenes are usually prepared by the Wurtz-type reductive coupling of dichlorosilanes with alkali metals.

Scheme 10

Although many kinds of polysilylene have been prepared by this method, the structure of the polymers is difficult to control.<sup>102</sup> Molecular weight and polydispersity are also unmanageable.<sup>103</sup>

Recently, several new methods of preparing polysilylenes have been reported. Transition metal catalyzed dehydrogenative coupling of hydrosilanes, especially of  $\text{RSiH}_3$ , is

promising (equation 100), although at this moment only oligomeric polysilylenes are available.<sup>104</sup>

The anionic polymerization of masked disilenes, that is, 1-phenyl-7,8-disilabicyclo[2.2.2]octa-2,5-diene derivatives, is

Scheme 11

also a new promising method for preparing polysilylenes with highly controlled structures (equation 101).<sup>105</sup> Indeed, a highly ordered alternating polysilylene copolymer, poly(1,1-dihexyl-2,2-dimethyldisilene) ( $\text{SiHex}_2\text{SiMe}_2$ )<sub>n</sub> (PMHS), has been synthesized for the first time by this method; an interesting thermochromism was observed for alternating polysilylene copolymers with a highly ordered structure.<sup>106</sup>

The anionic polymerization of masked disilenes proceeds *via* living anions, and therefore block copolymerization with a conventional vinyl monomer is possible. Recently, interesting hydrophobic block copolymer of PMHS with poly(2-hydroxyethyl methacrylate) (PHEMA) and poly(methacrylic acid) (PMMA) have been prepared (Scheme 11). These polymers can be self-assembled and are transformed into polysilane micelles,<sup>107</sup> shell cross-linked micelles (SCM),<sup>108</sup> and nanometer-sized hollow particles.<sup>109</sup>

## 6.2 Organic Synthesis

Applications of organosilicon compounds in organic synthesis are growing very rapidly. This topic has been discussed by several extensive reviews<sup>110</sup> and only some typical examples are listed here. However, it is meaningful to emphasize the importance of factors with which organosilicon compounds can be used for organic synthesis. These are: (a) silyl groups as proton substitutes, (b) stabilization of carbocations by  $\sigma$ - $\pi$  conjugation, and (c) stabilization of a carbanions by  $\sigma^*$ - $\pi$  conjugation. The nature of the latter two factors is discussed in Section 4.

### 6.2.1 Silicon as Proton Substitutes

Historically, silylation of ROH to  $\text{ROSiR}_3$ , was the first successful application of organosilicon compounds in organic chemistry. This kind of derivatization procedure has been used extensively for hydroxylic compounds such as sugars to give volatility in GLC (gas-liquid chromatography) and MS (mass spectrometry) applications.<sup>111</sup> In the beginning, the reaction of ROH with trimethylchlorosilane (TMSCl) in the presence of a stoichiometric amount of pyridine in toluene or benzene is employed for silylation. A combination of hexamethyldisilazane (HMDS) and TMSCl in a nonpolar solvent is more effective reagents.

Other commonly used trimethylsilylation reagents are: *N,O*-bis(trimethylsilyl)acetamide (BSA), *N*-trimethylsilylacetamide, *N*-trimethylsilylimidazole (TMSI), and *N,N*-bis(trimethylsilyl)urea (BSU) (Figure 12).

The rate of hydrolysis of  $\text{ROSiR}'_3$ , that is, the hydrolytic stability of silylated compounds, depends on the steric bulkiness of  $\text{R}'$ . An approximate order of steric bulkiness of common silyl groups is as follows: (Note that the order depends on the nature of the reaction and alcohols).<sup>112</sup>  $\text{Me}_3\text{Si}$  (TMS) <  $\text{PhMe}_2\text{Si}$  <  $\text{Et}_3\text{Si}$  (TES) < *t*- $\text{BuMe}_2\text{Si}$  (TBDMS) < *i*- $\text{Pr}_3\text{Si}$  (TIPS) < *t*- $\text{BuPh}_2\text{Si}$  (TBDPS) < *t*- $\text{Bu}_3\text{Si}$  (supersilyl) < (cyclohexyl)<sub>3</sub>Si. Therefore, *t*- $\text{BuMe}_2\text{Si}$ - and *t*- $\text{BuPh}_2\text{Si}$ - are frequently used as strong protecting groups in organic synthesis.

Hydrosilanes,  $\text{R}_3\text{SiH}$ , can be viewed as 'silylated hydrogen' and used as a reducing reagent. Hydrosilylation (equation 20) resembles hydrogenation in this sense. Reduction of prochiral ketones through hydrosilylation has been investigated extensively with platinum and rhodium complexes having

**Figure 12** Commonly used trimethylsilylation reagents

chiral ligand(s).<sup>113</sup>

Trimethylsilyl cyanide (TMSCN) and trimethylsilyl azide (TMSN<sub>3</sub>) are safe and convenient replacements for hydrogen cyanide and hydrogen azide, respectively, which are otherwise inconvenient or hazardous to handle.

Trimethylsilyl esters of Bronsted acids such as trimethylsilyl triflate and trimethylsilyl iodide are useful as catalysts for trimethylsilyl transfer reactions. An example is given in equation (105).

### 6.2.2 Stabilization of $\beta$ Carbocations

The most important and representative examples of this category are the reactions of allylsilanes (Scheme 4 and equations 106 and 107).

The regiochemistry of electrophilic attack to vinylsilanes is also controlled by the trimethylsilyl group.

Silyl enol ethers are useful for regioselective aldol-type condensation.<sup>114</sup>

### 6.2.3 Stabilization of $\alpha$ Carbanions

$\alpha$ -Metalated organosilanes can be prepared by addition of an organometallic compound to vinylsilanes, proton abstraction, halogen-metal exchange, and transmetalation (equations 42, 112–114).

These  $\alpha$  metalated organosilanes react with carbonyl compounds to give methylenated products.<sup>115</sup>

## 1 INTRODUCTION

The chemical symbol Ag is derived from the Latin *argentum*, which in turn originates from the Greek *ἀργός*, meaning shiny or glistening. Silver is a rather rare element in the earth's crust, and its abundance is only about 0.07 part per million. Native silver as a compact mass and 'horn silver' (chlorargyrite, AgCl), originating from chemical reduction and the action of salt water, often occur among sulfidic ores such as acanthite (Ag<sub>2</sub>S, the chief mineral), stromeyerite (CuAgS), proustite (3Ag<sub>2</sub>S·As<sub>2</sub>S<sub>3</sub>), stephanite (5Ag<sub>2</sub>S·Sb<sub>2</sub>S<sub>3</sub>), and margyrite (Ag<sub>2</sub>S·Sb<sub>2</sub>S<sub>3</sub>). Nowadays about 60% of silver is produced as a by-product in the processing of nonferrous metal ores such as galena (PbS) and copper pyrite (CuFeS<sub>2</sub>), and the rest by cyanide leaching of silver ores and recovery from coins and industrial scrap. Final purification is usually carried out by electrolysis.<sup>1</sup>

The photographic film industry accounts for about one-third of the world's consumption of silver. It is also used in making jewelry, silverware, artwork, mirrors, electrical and electronic contact points, and high-capacity Ag–Zn and Ag–Cd batteries. The metal and its compounds are useful as catalysts in organic synthesis. In medicine, silver sulfadiazine is effective for the treatment of burns.

Silver has a cubic close-packed structure ( $a = 408.626$  pm, space group  $Fm\bar{3}m$ ) and is the best conductor of heat and electricity among all metals. Being ductile and very malleable, it can be hammered into thin foils, which transmit blue-green light.

The chemistry of silver is in accord with its electronic configuration  $4d^{10}5s^1$ .<sup>1–3</sup> Silver is chemically less reactive than copper except toward sulfur and hydrogen sulfide, which rapidly tarnish lustrous silver surfaces. Silver is immune to nonoxidizing acids such as hydrochloric acid, but it dissolves readily in dilute nitric acid. However, concentrated nitric and sulfuric acids attack it only at higher temperatures owing to the formation of a rather insoluble protective layer of AgNO<sub>3</sub> or Ag<sub>2</sub>SO<sub>4</sub>. It dissolves easily in cyanide solutions in the presence of oxygen owing to a large shift in the silver potential (from +0.80 V to –0.31 V) in forming the complex  $[\text{Ag}(\text{CN})_2]^-$ . Some important properties of silver are listed in Table 1.<sup>3,4</sup>

## 2 SUBVALENT SILVER COMPOUNDS

Silver having a formal oxidation state smaller than one occurs in compounds with the most electronegative elements, namely, fluorine and oxygen. Disilver monofluoride (silver subfluoride), Ag<sub>2</sub>F, is formed in the reaction between finely divided silver and AgF in liquid hydrogen fluoride. It can also be obtained electrolytically from AgF at low current densities, crystallizing on the silver cathode as bronze-colored platelets. Ag<sub>2</sub>F decomposes into Ag and AgF above 100 °C. It has an *anti*-CdI<sub>2</sub> structure in which double layers of Ag ('metallic' Ag···Ag bond lengths lie in the range 2.814–2.996 Å) alternate with layers of AgF (Ag–F bond length is 2.451 Å). The compound is a good electrical conductor.

Trisilver oxide (silver suboxide), Ag<sub>3</sub>O, which conducts electricity, is made by heating AgO to 80 °C in a silver vessel in the presence of H<sub>2</sub>O under a pressure of  $4 \times 10^8$  Pa. Ag<sub>3</sub>O has an *anti*-BiI<sub>3</sub> structure in which oxygen occupies 2/3 of the octahedral holes in a hexagonal close-packed array of silver, in which the Ag–O bonds are 2.29 Å, while the Ag···Ag bonds are about 2.88 Å. Pentasilver orthosilicate, Ag<sub>5</sub>SiO<sub>4</sub>, is formed by hydrothermal reaction of silver powder with amorphous SiO<sub>2</sub> under high oxygen pressure.<sup>5</sup> Crystal-structure analysis showed that it should be formulated as  $[\text{Ag}_6]^{4+}(\text{Ag}^+)_4(\text{SiO}_4^{4-})_2$ , being composed of a packing of octahedral Ag<sub>6</sub><sup>4+</sup> clusters along with isolated Ag<sup>+</sup> and tetrahedral SiO<sub>4</sub><sup>4–</sup> ions. Silver also forms rare zero-valent carbonyl compounds Ag(CO)<sub>3</sub> and Ag<sub>2</sub>(CO)<sub>6</sub>, which exist only at low temperatures (10 and 30 K, respectively).

## 3 SILVER(I) COMPOUNDS

This is the dominant oxidation state of silver, and the Ag(I) ion with spherically symmetric configuration  $4d^{10}$  exhibits a range of coordination numbers from 2 to 6. Silver(I) is stable in aqueous solution as  $[\text{Ag}(\text{H}_2\text{O})_2]^+$ . However, the soft Ag(I) cation has a relatively low affinity

**Table 1** Properties of elemental silver

|                                                              |                                                                    |

for the hard aqua ligand, so nearly all its crystalline inorganic salts are anhydrous except for AgF and AgClO<sub>4</sub>.

Silver alkyls and aryls, together with silver(I) complexes of cyclic polyenes and alkynyl ligands, are generally classified under organometallic compounds. Stable silver(I) carbonyl complexes that have been characterized by X-ray analysis include [Ag(CO){B(OTeF<sub>5</sub>)<sub>4</sub>}], [Ag(CO)<sub>2</sub>{B(OTeF<sub>5</sub>)<sub>4</sub>}], and [Ag(CO){HB[3,5-(CF<sub>3</sub>)<sub>2</sub>pz]<sub>3</sub>}].<sup>6</sup> Silver acetylide (Ag<sub>2</sub>C<sub>2</sub>) complexes are described in Section 3.6.

### 3.1 Halides and Pseudohalides

Silver halides can be prepared directly by addition of X<sup>-</sup> to Ag<sup>+</sup> solutions, although AgF is usually prepared from silver oxide and hydrofluoric acid. The color and insolubility of silver halides in water increase in the order Cl < Br < I. Both AgCl and AgBr have the rock salt structure, though they are insulators. AgI has both zinc blende and wurtzite forms. The ultrahigh light-sensitivity of these halides (AgF only to the ultraviolet), particularly AgBr, is the basis for their use in photography. The formation of the linear [H<sub>3</sub>N–Ag–NH<sub>3</sub>]<sup>+</sup> complex can be used for the separation of mixed silver halides. Aqueous ammonium carbonate is sufficient to dissolve AgCl to give [Ag(NH<sub>3</sub>)<sub>2</sub>]Cl, while AgBr can be extracted with aqueous ammonia, in which AgI is sparingly soluble.

The halides AgX (X = Cl, Br, I) react with halide anions X<sup>-</sup> to give a series of discrete anionic complexes [Ag<sub>m</sub>X<sub>n</sub>]<sup>(n-m)-</sup>.<sup>7-9</sup> Examples of such iodo complexes are shown in Figure 1.
